impinge on yielding lung tissue, towards the formation of a smooth, circular boundary. Where formed in relation to the parietal pleura, some have their base upon the parietes, and bulge deeply into the elastic lung (Fig. 10). Multiple pockets may form, either as separate pockets or intercommunicating (Fig. 11). Some, however, produce an appearance very much resembling that of free fluid, and are produced by the walling off of a free effusion by adhesions; they are, as it were, a fixation of that process. Pleuromediastinal effusions show as localized widenings of the mediastinum sometimes parallel to the mediastinum, sometimes as a shadow with a border concave upwards and outwards, occupying the costophrenic angle.² Where formed in relation to a pneumonic process, as they often are, their shadows may be continuous with that of the consolidation. Even so, however, they have

the chest, Wessler and Jaches¹ give an excellent detailed classification of such loculated effusions. This may be summarized as follows,—

A. SUPERFICIAL EFFUSIONS OF PARIETAL ENCAPSULATED EFFUSIONS

- | | |
|--------------------|--|
| 1. <i>Axillary</i> | Either anterior or posterior. |
| 2. <i>Basal</i> | Tends to resemble a free effusion and to lack the more usual contour of pocketed effusions. |
| 3. <i>Apical</i> | Very apt to be mistaken for apical consolidations. Has a strong tendency to extend, and become generalized. |
| 4. <i>Mesial</i> | Lie up against the pericardium anteriorly. Apt to occur as a residual pocket after drainage of generalized effusions. |

B. CONCEALED EFFUSIONS—At no place related to the parietes.

- | | |
|--------------------------|--|
| 1. <i>Intrapulmonary</i> | or "Diaphragmatic." |
| | The most difficult to diagnose roentgenologically. |

2. *Mediastinal*..... Lying between the lung and the heart, or mediastinum. Differential diagnosis from mediastinal conditions difficult, but important.
3. *Interlobar* Sites,—
 - (a) in the oblique main fissure.
 - (b) in the horizontal right "middle" fissure.
 If progressive, tend to erupt to a bronchus, or to the general pleural cavity. Three clinical types exist,—
 - (a) Metapneumonic.
 - (b) Tuberculous.
 - (c) Idiopathic.
 Very difficult to discover or localize by physical examination alone.

C. MULTIPLE OR MULTILOCULAR EFFUSIONS

- Co-existence of several of the above.
- May be completely separate, or may communicate.
- Of clinical importance, as each requires to be individually drained.
- Separate pockets may contain different kinds of fluid.

Encapsulated effusions present a more difficult differential diagnostic problem than the free effusions, owing to their extreme variety. The diagnosis will often have to depend, ultimately, on exploratory aspiration of any suspected mass, after accurate localization roentgenologically. Lung abscess may produce somewhat similar appearances, but is intrapulmonary, has usually an irregular margin where it merges with the lung tissue, and may have a small air pocket. Plaques of dense pleural thickening arising as residues of old empyemata, are difficult to distinguish until they commence to show signs of calcification. They usually, however, lack the smoothly rounded contour of the actual fluid pocket. Benign, or relatively circumscribed malignant tumours of the pleura will practically always have to be differentiated by the absence of any causal history for an empyema. Most other lesions of the lung, tuberculosis, malignancy, syphilis, and the like, have their own identifying appearances, but here again, we have considerable difficulty where two

lesions co-exist. One minor point to note is to avoid confusing shadows of extrathoracic masses, as seen in posteroanterior films, for pleural densities.

Empyemata, if untreated, may absorb completely, leaving no trace. This occurs, though rarely, even with thick, purulent exudates, especially if there is a minimum amount of fibrinous plastic formation on the pleural surface. In the absence of spontaneous resolution, partial absorption may occur, and the remainder form a solid, dense, fibrous layer of thickened pleura, which ultimately calcifies. Such calcified plaques are common, and are exemplified by Figure 12. A rare example of complete pleural calcification is shown in Figure 13. With such a fibrosing or calcifying process, there occurs a bunching together of the ribs at the site of the lesion, and very frequently, a matting of the diaphragm across the costophrenic angle to the parietes, distorting and fixing the diaphragm; both of these are diagnostic points strongly suggestive of an old pleurisy.

Ordinarily, however, if empyema be left untreated, or if treatment prove ineffective, the disease goes on to the development of a chronic stage. The fluid may persist in closed pus pockets, and as such, act as foci of toxic absorption, and as a cause of vague ill-health. Much more often the cavity opens either into a bronchus, or on to the surface, or is opened, and persists for some reason or other. This results in a constantly or intermittently draining cavity with a persistent sinus.

In the examination of these cases, attention has to be given to the visualization of such cavities, and to the determination of their extent. This cannot be done by simple chest roentgenograms alone, as one has no method of determining the relative amounts of pleural thickening, and of fluid. It is necessary to inject the cavity with a contrast medium. There are three good media in use; lipiodol, or lipiodine, is certainly the most satisfactory medium. It can be diluted by equal quantities of olive oil or sesame oil; the

resultant 20 per cent solution affords ample density. Even so, however, in cavities of any size, this is an expensive method. A 20 per

the tube. The tube is then withdrawn, and the opening sealed over completely with collodion and absorbent cotton, be-

FIG. 11. Loculated empyema with multiple pockets. Separate drainage had to be established for each pocket.

FIG. 12. Calcified pleural plaque in right base. Three months history, many years ago, of a severe illness called "pleurisy."

cent solution of iodoform in sterilized sweet oil acts very satisfactorily, is easily made, and may possibly have a therapeutic value. Where neither of these is available, the ordinary water or water acacia emulsion of barium sulphate, as used for gastric fluoroscopy, is quite satisfactory, if sterilized. The various silver, or sodium iodide solutions and their like, may have some irritant action, and their use is not to be recommended.

Before filling, a cavity should be drained for a short time with the sinus in the most dependent position. The patient is then turned with the sinus upward, and with all necessary aseptic precautions, a fine rubber tube, attached to an ordinary 20 c.c. syringe, is passed as far as possible into the sinus. Any residual pus is aspirated, and then the cavity is filled slowly with contrast medium, until it overflows around

fore the patient is moved. As soon as the collodion has set, the patient can stand up, or even lie on the side of the lesion, without any escape of medium. The usual posteroanterior and lateral rays are then taken. In addition, however, a film should be exposed on the Potter-Bucky grid, with the patient in a position such that the sinus and the cavity are nearest to the film, using a lateral or oblique position as may be necessary. This not only gives a much clearer picture of the filled cavity, but also gives good visualization of the condition of the ribs at that point—an important point. Figures 14 and 15 represent two such visualized cavities, one posteriorly, and one laterally.

There are many causes for the persistence of a cavity. Of these, the most common is a thickened pleura rendering the walls rigid, and preventing expansion

of the lung (Fig. 16). A frequent concomitant of this, or existing by itself, is the presence of drainage established at some

shown by lipiodolization of the lungs, via the trachea, in the ordinary way. It should also be kept in mind that the condition

FIG. 13. Complete calcified cast of pleural cavity. Patient had a large empyema fourteen years ago. She was now sixty-four years of age, and had no symptoms whatever.

FIG. 14. Persistent empyema cavity injected with lipiodol. Condition postpneumonic, and persistence due to thickened pleura. Thoracoplasty, with decortication, resulted in cure.

point other than the lowest point of the cavity. Another possibility is the persistence of separate, unopened, unsuspected cavities. Sometimes one finds a foreign body, or a chip of bone at the bottom of the sinus. This is especially likely where there is a long narrow sinus, with no other apparent reason for failure to close (Fig. 15). These various conditions of the cavity may all be demonstrated by contrast filling, as described. Even in the absence of thickened pleura to bind it down, the lung may develop an intrinsic fibrosis which prevents its expansion. Communication between the cavity and a bronchus, either through an erupted abscess or through primary rupture of a loculated empyema, may complicate the process. Sometimes this can be demonstrated by injection of the cavity with lipiodol; at other times, the communication is best

of the ribs, or infection of the ribs at the old site of a resection, may be the cause of trouble.

The addition of a pneumothorax, partial or total, to any empyema process, is a common thing. This may occur in closed empyemata, after aspirating. Most commonly, however, in chronic pleural pockets, one finds air in conjunction with fluid, as partial pyopneumothorax. The presence of such air is of value roentgenologically in outlining the extent of any cavity, and in showing the degree of pleural thickening walling it. A characteristic feature of any such pocket is the so-called "fluid level." The upper surface of the fluid moves freely within the cavity and maintains itself horizontally, whatever the position of the patient. By examining the patient in several positions, the whole extent of the wall of the cavity can be accurately de-

terminated, and communication between multiple pockets identified. It is also worth noting that in certain cases of free

has done the same thing without roentgenologic assistance. By a correlation of these two groups of findings with each other,

FIG. 15. Persistent empyema sinus injected with lipiodol. Persistence was due to chip of bone in depth of the sinus.

FIG. 16. Old empyema cavity with perfect drainage, but rigid and thickened walls. Condition postpneumonic, and of thirteen years standing.

effusion, a replacement of whole or part of the fluid by air, may render visible any associated parenchymal lesions not otherwise demonstrable.

These, then, are the more common conditions found associated with infection of the pleural cavity. It is probably wiser for the roentgenologist to make as complete an examination as possible, before he takes any cognizance of the clinical facts. He can then make up his mind in an unbiased manner as to what he thinks the conditions are. Only thereafter should he consult with the clinician, who, meantime,

and with the history, it is usually possible to achieve a very accurate idea of what the real state of affairs is in the thoracic cavity.

THREE CASES OF NEUROMA:

CIRSOID NEUROMA OF FACE; NEUROFIBROMA OF STOMACH; POSTERIOR TIBIAL NEUROFIBROMA*

JAMES T. CASE, M.D., F.A.C.S., D.M.R.E. (CAMBRIDGE)

CHICAGO, ILLINOIS

AMONG the rareties of radiological practice are positive findings in cases of tumor of peripheral nerves. A description of three rare nerve tumors with positive radiological findings should therefore prove of great interest and importance, and, by stimulating more frequent recourse to x-ray study in neurological cases, should assist in increasing the frequency with which such tumors are recognized in advance of operation.

CASE I. EXTENSIVE CIRSOID NEUROMA OF FACE

Figure 1 shows the appearance of the facial tumor of H. D. K., a young man of twenty-six, on June 1, 1915 when he applied to me for examination of a swelling on the right side of the face. The patient stated that he was born with this deformity of the face. At the time of examination the right cheek was large, and the right eye so badly swollen that he could hardly see. All the tissues of the right side of the face were very much infiltrated and thickened. There was also a similar smaller tumor in the right supraorbital region. None of the swellings were painful. At the age of twelve, after having been thrown from a horse, striking on the head, the patient was unconscious for twelve hours. During the last eight or nine years, there had occurred a progressive enlargement of the growth. Seven years before the present examination two operations had been done without apparent success.

Roentgen examination of the skull in the anteroposterior direction failed to reveal asymmetry of the malar bones. Both right maxillae, however, were deformed by the pressure of the tumor, and the molars were distorted so that they pointed directly inward. The bicuspids were deflected to a lesser degree.

The lateral stereoroentgenogram of the head showed several well defined localized areas of decreased opacity of the cranial bones on the right side of the skull. One of these conspicuously thinned areas was located in the parietal

bone, two in the frontal bone, and one was apparently divided between the parietal and the temporal bones, the thinned out area apparently not in any way respecting the suture line. There was a distinct clouding of the right maxillary sinus, also a deformity of the upper and the lower maxillae on the right side, which were pushed inward by the mass of the tumor. The thinning of the bone is well shown in the roentgenogram (Fig. 2).

Careful neurological examination by Doctor W. H. Riley failed to reveal any neurological findings which were attributable to the tumor, aside from the defective vision. Examination of the eye grounds showed 20/60 vision in the right eye, 20/40 vision in the left eye. All the intraocular blood vessels showed a hyperemia, this being noted especially in the nerve heads. There was no particular difference between the two sides.

In considering the plan of treatment, it was decided to avoid hot water injections, at least until a histological diagnosis could be established, and to attempt the reduction of the tumor (1) by surgical removal of the large tumor beneath the right malar bone and the smaller tumor above the right eye, and (2) by treating the remnants of the tumor and the remainder of the involved areas of skin by roentgen-ray therapy, using what were then considered the harder rays and heavy doses, through a filter of 4 mm. of aluminum with an added 3 mm. of sole leather.

On June 3, 1915, we removed from above the right eyebrow what appeared to be a vascular tumor the size of a walnut. The tumor was adherent, on its under surface, to the periosteum of the supraorbital arch. The upper surface of the tumor seemed to be intimately associated with the skin in such a way as to make it difficult to find the line of division between tumor and skin. At the same operation there was removed from beneath the right malar bone an irregular globular mass 7 cm. in diameter, intimately adherent to the periosteum of the upper alveolar arch and to the anterior surface of the superior maxilla.

*Submitted for Publication February 27, 1930.

After three weeks, a further reduction of the tumor was attempted by means of the roentgen rays. The skin overlying the affected area was

neurofibroma or plexiform neuroma has been given, is practically always congenital. The upper eyelid, the cheeks, the region of the

so divided as to afford six portals of entry. Not only the face, but the areas of the skull which were shown by the roentgenograms to have been thinned, were subjected to roentgenotherapy. At first it was thought that a diminution of the facial swelling could be appreciated; but after some months of routine intensive therapy with the hardest rays then obtainable and with the filter above mentioned, this form of therapy was abandoned.

On November we returned the patient to the operating room for removal of as much as possible of the remaining tumor tissue. No recurrence having been observed since the last operation, we felt encouraged to do as radical a removal as possible, especially in view of the pathological report from Dr. A. S. Warthin. The result was fairly satisfactory from a cosmetic standpoint (Fig. 3); at any rate the patient expressed himself as well pleased.

The microscopic examination of the tissue by Dr. Warthin resulted in a report of a vascular fibrous tumor containing chiefly non-medullated nerve fibers, with muscle fibers in and between nerve bundles (Figs. 3, 4).

This form of tumor, to which the name cirroid

ear, the back and the breast are the principal sites of this type of neuroma, which often causes curious deformities, as in the nape of the neck, the face, the extremities and the external genitals. Bruns was first to apply the term cirroid to this type of nerve tumor, composed of plexuses of convoluted strands or cords held together by a soft, loose, fatty connective tissue. Although it may be found as a more or less circumscribed tumor-like mass, it may present, as in this case, no capsular or other limitation, perforating the neighboring fasciae, penetrating the muscles in all directions, adhering to the periosteum, and lodging in grooves or foramina in bone, as the flat bones of the skull or the roof of the orbit. It may be very intimately connected with the overlying skin which may be much thickened (Alexis Thompson). All the foregoing characteristics were presented in the case herewith reported. Of a series of 58 cases reported by Thompson, 18 occurred in the temple, forehead and upper eyelid; 14 in the posterior part of the neck and behind the auricle, 4 on the nose and cheek, 5 in the lower jaw and anterior half of the neck, 8 in the breast and back, and 9 in the extremities.

In spite of the apparent futility of the radiation therapy in this case, as judged by

the result in 1915, the afterhistory of the case and the clinical results in other cases of fibromatous tissue under roentgenotherapy,

near the pylorus, having the appearance similar to that noted in some cases of large gallbladder compressing the wall of the

lead us to suspect that after all it may have been the roentgenotherapy which has been chiefly responsible for the failure of the tumor to recur. The patient was alive and well according to a letter received in the fall of 1929, although he has not presented himself for a photograph of his present appearance. No further treatment with x-rays has been administered in the intervening fifteen years. Fig. 5 shows the final result in December 1915.

CASE II. GASTRIC NEUROFIBROMA

Mrs. M. L., age 47, presented herself in May 1926 for relief of indigestion and epigastric pain. The clinical symptoms led to a radiological examination of the gallbladder by Graham's intravenous method which resulted in a diagnosis of multiple non-opaque gallstones, practically filling the gallbladder. The gallbladder appeared to be of unusually large size (Fig. 6, a). A gastrointestinal x-ray study was also carried out without any report of a pathological finding. A small, shallow filling-defect, was seen on the greater curvature

FIG. 5. Appearance of Case 1, at close of surgical and x-ray treatment in 1915. No essential change to the present date.

stomach; and in this case it was thought to be due to the pressure of the large gallbladder

(Fig. 6, b, c, d). The filling-defect seemed to be more or less ovoid and with borders that gradually faded into the density of the gastric

from the posterior wall of the stomach and the wound closed in the transverse diameter. At the time of operation the mass was thought

FIG. 6. Case 11. (a) Cholecystogram showing multiple non-opaque gallstones. (b) and (c) Faint filling-defect in greater curvature of stomach shadow, really due to gastric neuroma on posterior wall, but erroneously interpreted before operation as being associated with pressure from the stone-filled gall-bladder. (d) Another film from the same series showing a high grade of spasm in the stomach at the site of the neuroma.

shadow, thus suggesting an extrinsic rather than an intrinsic cause.

At operation by Dr. W. E. Shackleton, of Kalamazoo, Mich., on May 11, 1926, a moderately distended gallbladder filled with stones was removed, and on examination of the stomach there was found on the posterior wall a tumor mass near the pylorus, 6 cm. in diameter, without any palpable glands in the neighborhood. The tumor mass was resected

to be malignant but Dr. Warthin's report on the histology of the tumor was that of a neurofibroma, primarily a disturbance of development (Fig. 7).

G. Lardennois¹ in 1928 reported a gastric neuroma removed by gastrotomy but which before operation was reported by Henri Bécclère as a benign tumor on the basis of the roentgenographic findings. A woman of 58 gave a history of a gastric hemorrhage, followed

by melena of definite grade. The patient then recalled that on previous occasions she had noted dark blood in the stools. She had never

to 1927 Balfour and Henderson² were able to report 38 cases of benign gastric tumors.

Our failure to recognize the definitely gastric

FIG. 7. Microphotographic appearance of the gastric neuroma of Case II.

vomited and there had been no gastric disturbance of a painful nature. Following the definite hemorrhage with black stools, there continued to be a leakage of blood at the site of the tumor as shown by constantly positive occult blood findings in the excreta. On a tentative diagnosis of duodenal ulcer, Bécclère made a radiological study resulting in the finding of a clear zone, giving the impression under fluoroscopic manipulation of a polypoid growth implanted in the gastric wall. A re-examination confirmed the opinion that one dealt with a benign tumor. Operation confirmed the opinion. The author removed from the anterior wall of the stomach in its middle third a tumor the size of an apricot which on histological examination proved to be a peripheral glioma, included within the thickness of the muscular wall. The bleeding had its origin in a mucosal ulcerated area in the most exposed part of the prominence of the gastric wall caused by the tumor.

Statistics from the Mayo clinic indicate that there occur one benign tumor of the stomach to about eighty malignant growths. From 1922

FIG. 8. Roentgenogram of left leg, showing normal bony structure, and a soft tissue tumor (at arrows) between the bones and the Achilles tendon, proved to be a neurofibroma of the posterior tibial nerve. The tumor caused definite local displacement of the calcified posterior tibial artery.

origin of the tumor in our Case II, illustrates how important it is to commence every radioscopic study of the stomach by careful palpation under the screen at once after the first swallow of the opaque meal, for when the full meal has been ingested it is much more difficult to recognize a tumor, especially when located on the posterior wall.

CASE III. NEUROFIBROMA OF THE POSTERIOR TIBIAL NERVE

This case, though previously included in a report³ on false peripheral neuromata, is referred to here because of the interesting radiological finding. Mr. A. P., age 63, came to me in August,

1927, for treatment of a neuritis involving the left leg and foot. There was found a rounded swelling about 2 cm. in diameter, on the left leg just above the ankle, most evident on the internal aspect of the member. The tumor was movable laterally to a limited degree, but not at all in the long axis of the leg. It was not attached to the skin, and was not sensitive to gentle pressure. Pinching or hard pressure caused intense pain to shoot into the foot. The lump was first noticed about twenty years before admission, and was much smaller then than at the time of examination, having undergone gradual though slow growth. Roentgen-ray study (Fig. 8) did not reveal any abnormality of the bones of the leg or ankle, but it did show distinctly the presence of a soft tissue tumor between the shadow cast by the Achilles tendon and the bones of the leg, causing a local displacement of the neighboring calcareous posterior tibial artery, the soft tissue shadow corresponding accurately to the palpable painful tumor. The findings led to a diagnosis of neuroma of the posterior tibial nerve.

Under local anesthesia the posterior tibial nerve was exposed through a longitudinal incision on the inner side of the left leg just above the ankle. The nerve was found to surround a well-encapsulated, fusiform tumor about 3 cm. in diameter. The sheath of the nerve was split longitudinally and the tumor enucleated with very little traumatism to the nerve tissues.

The pathologist's report on the tumor indicated a pure neuroma in some areas, neuroglia in others. No ganglia cells were found, although there were atypical neuroblasts. The nerve fibers were chiefly non-medullated. Throughout the tumor there were large and atypical lymphatics and blood vessels. Some bloodvessels showed some hyaline change in the walls, a cylindromatous change. There were also areas of myxomatous tissue scattered throughout the growth and some pigmented areas from old hemorrhage. The general structure was that of a congenital disturbance of development resembling the cirroid neuroangioma (Warthin).

SUMMARY

Three cases of nerve tumor, of the

neurofibroma variety, two of them having characteristics resembling cirroid growths, are reported to illustrate the value of the roentgenological study in a field where x-ray aid is not ordinarily sought.

In an extensive cirroid neurofibroma of the head and face, the roentgen study revealed extraordinary thinning of the cranial bones and distortion of the upper and lower jaw and the teeth of the affected side of the face. The long duration of apparent freedom from recurrence following combined surgical and roentgenotherapeutic attack fifteen years ago, in spite of recurrence and continued growth following previous treatment by surgery alone, suggests that it is worth while treating such neuromas by x-ray or radium alone or as a supplement to surgical intervention according to the case.

A fairly large neurofibroma of the posterior wall of the stomach near the pylorus was missed in the pre-operative x-ray study because of the spectacular finding of a large gallbladder filled with stones and the assumption that this large gallbladder was the cause of the filling-defect in the greater curvature aspect of the stomach near the pylorus in reality due to the neuroma.

A neurofibroma of the posterior tibial nerve was well demonstrated in the roentgenogram by its faint but well-defined shadow in the soft tissues of the leg, and especially by its displacement of the posterior tibial artery rendered visible by an unusual grade of calcareous degeneration.

NOTES ON THE ETIOLOGY OF CANCER*

ALBERT SOILAND, M.D., D.M.R.E. (CAMBRIDGE)

LOS ANGELES, CALIF.

NEVER before in the world's history has the subject of cancer been under closer scrutiny than at the present time, for practically every educational group of higher intelligence the world over is making a sweeping investigation of all the available data which may have bearing upon the whole cancer problem. The writer, therefore, takes the liberty of submitting a few notes on this subject, some of which are purely empiric, but are gleaned nevertheless from a personal clinical experience with cancer over a twenty-five year period, and upon a fairly large representative cancer group.

What influence has mechanical irritation upon the production of cancer? In the writer's opinion, the importance of this has been greatly overestimated, even to the point of assumption that its part in the production of a latent cancer may be considered negligible. With chemical irritation we believe that we can also take a similar though somewhat modified view. This whole subject is still so insecure that one hesitates to inject personal opinion, yet withal is so important that this phase cannot well be omitted from any article dealing with the theory of cancer causation.

Our partner, Dr. O. N. Meland, offers the following discussion on the effect of chemicals:

"What effect chemicals have in the production of cancer is a difficult question to answer offhand. Certain it is that only a very few individuals who are exposed to chemical irritants develop malignant disease. Observation of those who are engaged in industries where the skin is subject to the products they are preparing, shows that the products of coal tar distillation seem to be one of the offending elements.

"Thus, we have the paraffin cancers in the paraffin workers, the chimney sweep's

cancer due to scrotal irritation from soot, and of workers engaged in these pursuits, only a small fraction develop malignant skin lesions, and those come after a long period of exposure.

"Experiments on mice and rats reveal that a small number will develop skin cancer after prolonged painting with tar, but rabbits and guinea pigs, when subjected to the same chemicals, practically never develop anything suggestive of a surface cancer. This leads us to believe that whatever rôle the chemical plays, it must be a minor one, or rather it is merely an exciting agent. In other words, the soil must be prepared before irritation will bear fruit.

"What the underlying factor is, no one knows, but it probably is hereditary in nature, as Doctor Maud Slye has demonstrated in her work of twenty years with mice. Whether the irritant factor is to be followed by cancer will depend upon what the cell has hidden within itself. If a susceptibility exists and has been handed down through the germ plasm, then a long continued irritation by any one of a variety of chemical or physical stimuli may be followed by cancer in these unfortunate individuals."

Combined mechanical and chemical irritations will without question so damage cell structures at the point of contact that any infection may well prosper there, but what have these factors to do with the residual, hereditary, or sleeping cancer cell without which, in the writer's opinion, no cancer growth could prosper? If this view should prevail, then our time spent in seeking a specific germ, or by the same reasoning a curative or preventive serum from such, is wasted. This does not mean that carcinoma is considered to be in the nature of an infection, but that infection

*Submitted for publication February 27, 1930.

plays a very important rôle in the incidence of cancer. It is therefore obvious that its removal together with its cause, materially improves the patient's condition and renders much more probable the successful destruction of the cancerous process itself.

Can one draw any conclusions as to the cause of cancer from a study of the tissues in the regions where cancer most frequently originates? Let us briefly consider this question in the ratio of its selectivity: in man, the face, lip, tongue and stomach; in woman, the breast and the uterus.

In the skin, the face is the location of choice for epithelioma. Here irritation of all sorts, it must be admitted, is more probable than on the covered and protected parts. Even the hands are less exposed, as they are frequently in a man's pocket or in a woman's glove. Therefore, the face is always in the weather and meets all external attacks from the front. Hence, prominent features of the face are usually the seat of local abrasions, irritations, infections, and then epithelioma.

How much do the irritating factors in this illustration contribute to the development of epithelioma? If the writer's opening statement be accepted, that irritating factors play only a minor part in the role of cancer production, how can one reconcile this to the apparent fact that cancer of the skin occurs most frequently upon the face, and the face is almost continually subjected to the irritating factors enumerated?

Conversely, we know that approximately ten percent of the human race acquires cancer. However, this ten percent includes cancer distributed in all parts of the body. Hence, we must rightfully assume that much less than ten percent of all cancer, and even less than five percent, actually originates in the skin of the face.

If, therefore, irritation is considered an important agent in cancer production, why does not the other ninety-five or more percent of the human race, whose skin is equally exposed to irritation, devel-

op cancer? It is this large discrepancy in figures which cannot be lightly laid aside when one is attempting to analyze the brief available facts already accumulated concerning cancer.

The daily shave of men is certainly a decidedly irritating factor where the skin is constantly bruised and frequently injured. Yet, we have no evidence to show that the ratio of epithelioma is greater among the shaved than the unshaved. Similar irregularities to which the tongue is subjected may have a strong bearing upon the incidence of cancer in this organ; yet here we have the added irritation with food products of extreme temperatures and of a kind and degree never intended by nature as fit for human consumption. Surely the external skin is never subjected to such unnatural stimulation, and if this were a predominating influence in the production of cancer, nearly every male individual, and not a few females, would develop epithelioma of the lip, tongue, or mouth.

The lower lip in man is predominant in primary cancer, which ordinarily begins at the junction point of skin and mucous membrane; possibly this may be a locus minoris resistentia or a weak spot in the fusion line of the respective epithelial cells. Here we have present not only the external irritation alluded to, but also such injury as may arise from careless mouth hygiene, use of tobacco, carious teeth, and other insults.

We may as well here include the stomach. This organ chooses the region of the pylorus as its objective for carcinoma. At this point the mucous membrane of the stomach fuses with mucous membrane of the duodenum; still cancer does not select this fusion point as its most frequent habitat but seems to invade more frequently the lesser curvature proximal to the sphincter. In the stomach, however, we have two distinct but powerful irritating factors—the muscular or mechanical, and the secretory or chemical. These, together with abnormal food contacts, make a formidable array of irritants which

would soon decimate the human world which we now term civilized, if they alone were the causative agents of cancer.

As has already been pointed out, cancer of the skin in early womanhood is relatively rare, much more so than in early manhood. In woman it is difficult to say which organ exercises the predominating influence the breast or the uterus. From the literature, one would adduce that the two run almost parallel. In our own experience, we are certain that we saw more uterine than breast cancers in the earlier years of our work, while during the past decade the breast cases have been steadily increasing in number so that at the present time the breast cancer cases outnumber the uterine cases. This is perhaps due to the fact that in former times the early bleeding from the uterus caused more alarm and brought the patient to the physician, whereas now women are being taught to bring the early lump in the breast to the attention of their medical adviser.

In child-bearing women, the cervical canal more than any other pelvic part is subjected to severe strain, irritation and injury; yet primary carcinoma prefers to take its origin from some part of the cervical lip, and by no means does it routinely arise from the seat of a cervical tear. In the corpus uteri, it is questionable whether child-bearing is a priori an irritating cause of cancer. We ourselves believe that a degenerating fibroid is a greater factor than formerly believed. Again, we have to ask ourselves, if irritation has a direct bearing upon cancer causation. Why are ninety-seven percent of child bearing women immune, assuming that we allow the large and arbitrary

three percent basis for cancer of the uterus out of the gross total of all cancer which involves the human race? The same reasoning can be applied to cancer of the breast.

Theodor Boveri's "Chromosome Theory" is one of the most ingenious dissertations on the morphology of cancer which we have seen. Throughout the little book, so interestingly written, are many convincing statements, and the theory propounded is not unreasonable and it opens up a wide field of speculation. It seems to have a sound basis and can very well be harmonized with the hereditary theory of Doctor Maud Slye. The latter is, in the writer's opinion, the one outstanding contribution to the incidence of cancer which has successfully withstood adverse criticism. The test of time also seems corroborative.

If we can disregard irritation alone as a primal cause of cancer, may we not assume that two additional factors have to be reckoned with. First, that the types of cancer under discussion show a predilection for a junction point of two epithelial structures, and second, the combined action of constant irritation and physiological function at such points brings on early senility of the cells in these parts so as to invite cancer development.

Finally there seems to be a tendency to turn toward the endocrine system which may after all be the sole custodian of the secret. Here we have the complex mechanism which reigns over the rise and fall of the whole complicated cellular structure, and it is sincerely to be hoped that further studies along this line may bring us nearer our goal.

ROENTGENOLOGY OF THE ACCESSORY NASAL SINUSES*

DORWIN LEWIS PALMER, M.D.

PORTLAND, OREGON

THE passing decade has proved the importance of eradicating foci of infection. The teeth, the tonsils and the gallbladder have been intensively studied, that the presence of foci might be discovered; and now we find the attention of the medical man, the otolaryngologist and the radiologist centered upon the accessory nasal sinuses. In this brief communication it is our wish merely to recall to attention a forgotten technique, and not to enter into the statistics of a considerable series of cases studied in this manner, nor to undertake a discussion of gross and microscopic anatomy. This we propose doing in a later communication.

The roentgenologist made a large effort to study sinus disease even before he obtained any cooperation from the otolaryngologist. This field, in common with all other fields in medicine, could not be studied by any one specialized group. There must be an active and whole hearted cooperation between all who are concerned, if any important work is to be done. It is only during the past few years that this essential cooperation has existed.

From the mass of ideas of the past to the present time there has come no technique which satisfactorily demonstrates pathology in the accessory nasal sinus. We then arrive at the point where we must choose the procedure which meets our needs best. This each roentgenologist does, and, in consequence, there are more variations of procedure in the study of sinus disease than any other in roentgenology.

The writer has gone through the evolution of this subject along with others, having worked with flat, posterior-anterior, and lateral films, the occipito-mental position; with the 107° angle of Granger, without being able to give to the otolaryngologist the information which he desired.

We were able to give fairly accurate information regarding the antra and the frontal sinuses but practically nothing

FIG. 1. Shows position of head for films of the antra.

concerning the extent of involvement of the sphenoids or the ethmoid labyrinth. The occipito-mental position for the study of the sphenoid shows very little except increased density because of the multiplicity of overlying structures.

Granger's method is, in his hands, very satisfactory, but this position, it seems to us, is a special study and not satisfactorily adapted for routine examinations—a requisite which must influence the selection of a method.

We attempted to modify Granger's work by making three films in the postero-anterior position, one film at Granger's 107° angle, one at an angle of 90° and still another at 35° . Each of these films could be utilized in the stereoscope. This change gave us more information than flat films, but shadows of structures were present which we could not study properly and the clinicians' verdict was that the method did not give them the information they desired.

* From the Departments of Radiology and Otolaryngology of the Portland Clinic. Submitted for publication February 27, 1930.

In 1925 we began to work with the Rhiese technique. This technique has been rediscovered at varying intervals since its

exposure tunnel are parallel. The central beam is directed from the opposite parieto-occipital region through the orbit which is

FIG. 2.

FIG. 3.

FIGS. 2 and 3. Show the position of the head and its relation to the sinus board in the Rhiese position. The position is reversed for the left side.

original description and is an oblique exposure of the head. The patient's head is placed on the exposure tunnel with the sagittal plane of the skull at an angle of

in contact with the exposure tunnel. Both sides are done stereoscopically. This position projects both the ethmoids and sphenoids through the orbit. One sees the optic

FIG. 4. Shows the normal ethmoid labyrinth beneath the orbital plane, the sharp clear borders of the sphenoids anterior and below the optic foramen.

about 23° with the tunnel. This elevates the occiput and places the external orbital margin, the nose and the chin in contact with the tunnel.

The plane of the small cone and of the

foramen on the same side, the superior and posterior margins of the sphenoid, and the ethmoid labyrinth. The ethmoids are overshadowed by the sphenoid and the ethmoid cells from the opposite side, but one is per-

mitted to separate these structures by the use of the stereoscope.

It is obviously impossible for the roent-

containing air and having sharp, clear-cut margins, while involved cells will show a definite blurring of the intracellular trabec-

FIG. 5. Shows a chronic hyperplastic ethmoid and both sphenoids. Note the blurring of the margins of the sphenoids and the moderate thickening.

genologist even to translate into terms of roentgen pathology the anatomical pathology present in the sinus, unless he can follow the patient to the operating room or have the benefit of a postoperative conference with the surgeon. At this conference the surgeon must describe minutely the changes which were present and he and the roentgenologist must fit these changes to the varied structural distortions noted on the films. This process of education each roentgenologist must go through if he is to equip himself to give satisfactory opinions. It is not sufficient that he should have the necessary mechanical equipment.

The uninvolved sinus contains air; shows no degree of opacity; the margins of the cells are sharply outlined. We are all familiar with the appearance of the uninvolved antrum and frontal. The ethmoid labyrinth, as shown by the Rhiese position, when uninvolved, will demonstrate the individual cells of the labyrinth

ulae, just as seen in studying the mastoid structure.

The sphenoid, uninvolved, is well illuminated and the posterior and superior borders are sharp and clear. The involved sphenoid, may or may not show a density, but the margins will be blurred or thickened.

In study of these, or for that matter, any sinus film, there are two changes from the normal: First, *an increase in density*, which may vary from a change so slight that it is barely perceptible to a complete opacity. This type of case, however, is one in which nasal examination reveals to the otolaryngologist unmistakable evidence of disease and films are requested principally that the anatomy of the sinus and the extent of involvement may be determined. Second, *slight change in structural characteristics*. This is the type of case in which the internist finds evidence of infection. The patient gives but meager subjective symptoms of sinus disease; and the objective evidence, at nasal examinations,

is not definite. These are the cases that the roentgenologist must prove or disprove if he is to give a real service. To do this we

observe filling defects on the posterior wall, in the Rhiese position, that are not evident in the antero-posterior position.

FIG. 6. Same patient as shown in Fig. 5, with the left sphenoid injected. Note the space between the lipiodol and the bony margins, and the relative positions of the two sphenoids in both views.

must have films which are technically as nearly perfect as possible—films made in a position which will demonstrate to the maximum degree the sinus anatomy; and we must be thoroughly familiar with the roentgen findings in the normal sinus.

In this type of sinus involvement the changes may be only a blurring of the normal sharp, clear borders of the antra, frontals and sphenoids, and of the sharp, intracellular trabeculae of the ethmoid labyrinth; or there may be a definite thickening of the margins and a lack of ethmoid structure. It is the careful study of structure and detail that enables us to give a valuable opinion.

There are many times that our routine examination must be supplemented by the use of some contrast media, for instance lipiodol. In the selection of position for this examination we can find no reason to discard either the Rhiese or Waters positions, for here we have an opportunity to study all the sinuses in both the anterior, posterior and oblique positions. Frequently we are able to

Summary. Experience with other methods of sinus examination has brought us to the firm conviction that, at least until a more satisfactory method is devised, the Rhiese position, when stereoscopic films are made, is the most valuable for the routine study of the sphenoids and the ethmoids, and that flat or stereoscopic films in the postero-anterior direction after the manner of Waters gives sufficient dependable information regarding the maxillary antra and the frontal cells.

It has also shown us that the study of margins and structures is of greatest importance; that each individual working in this field must study carefully the anatomical pathology of the cases operated which he has previously studied radiographically; and, lastly, that dependable diagnoses are obtained only when the otolaryngologist and the roentgenologist study the cases together, making a complete opinion from the clinical and roentgenological evidence available at their consultation.

A NEW COMBINED TECHNIC FOR RADIOLOGICAL EXPLORATION OF THE GALLBLADDER

M. ROSES ARTAU, M.D., F.A.C.P.

SAN JUAN, PORTO RICO

AFTER two years of careful observation, I have reached the conclusion that the usual technic for the exploration of the gallbladder with and without the administration of iodeikon or one of the other preparations utilized for cholecystography may give rise to error, or to doubts which are as prejudicial as errors.

Once the roentgenogram has been made without the previous administration of iodeikon, one either sees nothing or makes out a dark shadow with uncertain contours or he attempts to define the position of the organ by a crescentic deformity of the duodenal bulb in case a barium meal has been given simultaneously, with the result that the flat roentgenogram often proves to be a problem in which all the other problems are combined without clearly setting forth anything.

Sometimes one obtains clear shadows of gallstones, negative or positive, and at other times one obtains the shadow of the gallbladder by virtue of the characteristics of the bile which it contains or the roentgenological conditions of the gallbladder walls; but always one is involved in doubt. Above all one is impressed with the insecurity of the procedure. Bile plus the iodeikon is sometimes sufficient to hide the gallstones.

Making various observations with gallstones of different morphology, dimensions and chemical nature, placed within a small parchment sac, between water bottles equivalent to the coefficient of absorption of the walls of the body, and having obtained roentgenograms with satisfactory technic, it has always been possible for me to obtain sufficient shadows to indicate the presence of the stones. Filling the little sac with bile of various characteristics on various observations nothing appeared or one was simply able to make out the shadow of the artificial gallbladder, which gave one information regarding its position, size and

morphology. Gallstones were only visible when they were of cholesterine or bilirubin plus calcium.

These observations suggested to me a combined procedure which I have practiced frequently with very satisfactory results, and by means of which, moreover, it was possible to reach the necessary logical conclusions to sum up these delicate and difficult studies.

Utilizing the non-surgical biliary drainage of Lyon, the gallbladder is emptied and its contents collected aseptically, after which I expose a series of films under certain definite conditions. I then administer iodeikon either by oral or intravenous route. In some cases, I leave the sound in the duodenum exposing the films with it in place, and by it I slowly inject the iodeikon preparation and at the appropriate hours make new films, administer a barium meal and continue my observations while I do a chemical and bacteriological study of the bile.

The work once done I find myself in condition to establish conclusions concerning the following points:

1. Permeability of the common duct and a functional test.
2. Cytological characteristics of the bile.
3. Bacteriology.
4. Permeability of the cystic duct.
5. Morphology of the gallbladder, anatomical relations, adhesions.
6. Presence or absence of gallstones.

The trouble to which the sum of all this puts the patient is relatively slight when compared to the great benefits which may be derived from establishing a combined diagnosis.

This modest contribution to the non-surgical diagnostic exploration of the gallbladder I offer in the hope that it may merit the compliment of approval and adoption in practice.

PLEURISY IN INFANTS AND CHILDREN*

RADIOLOGICALLY DEMONSTRATED

E. GORDON STOLOFF, M.D.

NEW YORK

ACUTE PLEURISY

DRY OR FIBRINOUS PLEURISY

THE pleurae are not roentgenologically visible in their normal condition and relationship to the other parts of the chest. With the deposition of fibrin, however, even in thin layers a shadow outlining the affected part of the pleura is cast. This is seen as a fine hairline density closely adjacent to the lateral thoracic wall or in the regions of the interlobar fissures. It may be encountered early in a pneumonic process with which pleurisy is associated or later when it is residual to an effusion, serous or purulent. Such hairline shadows are frequently seen in children who have undergone tuberculous pulmonary infection; the pleural thickening overlies a primary focus, a diseased lymph node or a site formerly epituberculous. When part of or the entire surface of the pleura is affected there is a faint homogeneous veiling of the lung over the affected part.

FREE EFFUSION IN THE PLEURAE

SEROUS OR NON-PURULENT PLEURISY

The initial roentgenological evidence of free serous effusion always manifests itself at the most dependent portions of the chest, in the costophrenic sinuses of the bases. (Fig. 1.) The normally sharp outlines of the diaphragm and costal wall become obscured by a homogeneous shadow which is faint or dense, depending on the amount and depth of the fluid present. The effusion may remain limited. It may increase in amount and extend upwards in the pleural cavity and manifest the extension roentgenologically by an increasing height, width, and density of shadow. From the highest point of the effusion, which lies

laterally in the axilla, the shadow slopes downwards to its most medial point on the diaphragm. In this way is formed the appearance of a triangle whose hypotenuse faces the mediastinum with a more or less convex border. This is the result of:

1. The gravitation of the fluid to the most dependent parts (the posterior and postero-lateral parts.

2. The elastic tension of the lung which pulls on the surface of the fluid causing the most elevation in the axilla where the tension is greatest (Wessler and Jaches).

3. The fact that the inferior lobe is largely posterior and is first to suffer compression towards the mediastinum, thus permitting the largest fluid accumulation in the posterior and postero-lateral portions.

The demarcation of the fluid accumulation is sharply defined in the small and moderate sized effusions. As the amount of fluid increases, the compression and atelectasis of the adjacent margin of the lung increase; a pulmonary shadow is therefore cast which creates a haziness of the otherwise sharp line of the fluid margin. The medial line of fluid effusion not only becomes less sharply defined with increasing quantity of fluid, but tends to become less convex and more horizontal in position. Characteristic of all large effusions is a displacement of the heart and superior mediastinum towards the opposite side, with a depression of the diaphragm of the same side. Shadows cast by fluid are homogenous and dense, obscuring all lung markings. The opacity is greater even than that of pneumonic infiltration and approximates that of caseation.

Associated with the accumulation of large amounts of fluid in the pleural cavity is a widening of the interspaces,

* From the Department of Pediatrics (Dr. Schick) and the Department of Radiology (Dr. Jaches) the Mount Sinai Hospital, New York. This article will be part of a chapter in the author's forthcoming book on "The Chest in Children, Roentgenologically Considered" to be published by Paul B. Hoeber, Inc., N. Y., 1930. Submitted for publication February 27, 1930.

and a fullness and immobility of the affected side, observed fluoroscopically, which is characteristic for such effusions

contain only a small amount of free fluid. It appears as a band- or ribbon-shaped shadow adjacent to the thoracic wall, due

FIG. 1. Free pleural effusion of moderate extent at left base.

in children. In the early stages of effusion the reverse may be true; one may see a narrowing¹ of the interspaces, which together with a relatively narrowed and immobile chest suggests there is a reflex attempt to modify or arrest the pain of pleural involvement.

PURULENT PLEURISY OR EMPYEMA

Empyema may arise in three ways:

1. From a serous effusion which has become purulent.
2. From the rupture of an abscess into the pleural cavity.
3. From a fibrinoplastic exudate arising in pneumonias.

In the first two instances the X-ray appearance does not differ from that of a serous effusion; purulent effusions cannot be differentiated roentgenologically from serous effusions. In the third instance, there is a shaggy fibrinoplastic exudate on the visceral pleura the interstices of which

to the separation of the lung from the chest wall by the fibrinoplastic exudate. This is an early sign of empyema and may antedate the appearance of suggestive physical signs and the presence of free pus on exploration. The shadow may at first be relatively narrow and uniform in width; later it widens and becomes broadest at its base as its fluid content increases and gravitates to the base. The rest of the lung field is clouded if the exudate encases the entire lung or one side of the lung. The peripheral band-like shadow is often seen even in those instances of exudation over the entire lung surface because the rays traverse the entire thickness of the exudate on the edge of the lung, thus causing a summation of the shadow on the posterior axillary, axillary and anterior axillary surfaces. The fibrinoplastic exudate may lie over the upper lobes alone, the lower alone or both. It may be seen over the lower lobes when the

pneumonia affects the upper lung, or over the site of the pneumonic infiltration in which case it is extremely dense on

tic exudate of inflammatory processes leads to the agglutination of opposing surfaces to form sacculations in contra-

FIG. 2. Encapsulated effusion. Generalized haziness of entire left lung due to early acute pleural affection.

account of intensification by the infiltration. As the amount of free pus increases it approximates more and more the appearance of a free serous or purulent effusion. The demarcation of the diaphragm disappears so that the liver opacity blends with that of the exudate, a sign which during lower lobar pneumonia may be considered as characteristic of empyema (Wessler and Jaches). In the so-called pleuropneumonia there is present early in the course of the disease an extensive, thick, shaggy, fibrinoplastic exudate over the affected lung which appears roentgenologically as a very dense and very broad peripheral band-like shadow with an irregular medial margin. The clinical course is prostrating and early empyema or exitus occurs.

ENCAPSULATION OF EFFUSION

Infection plays the decisive rôle in the determination of encapsulation. The plas-

distinction to the transudates of cardiac diseases (Wessler and Jaches).

Encapsulation of purulent fluid is common in the earliest years of life. The effusion may be superficial in the general pleural cavity in contact with the costal wall, or deep (concealed) and not in immediate contact with the costal wall. The apical, basal, and axillary encapsulations are superficial; the interlobar, mesial, mediastinal and infrapulmonary encapsulations are deep. Physical signs of the presence of superficial ones are easy to elicit while those of the concealed encapsulations may defy recognition unless one resorts to roentgenography.

SUPERFICIAL ENCAPSULATED EFFUSIONS

Encapsulated effusions which are superficial may occasionally present the appearance of free fluid collections with the tapering fluid borders. The usual appearance, however, is that of homogeneous, dense, more

or less globular or ovoid shadows the shapes of which are modified by the contiguous structures and adhesions. When a

effusion but the presence of râles due to resolving infiltration and unretracted lung confuses the issue so as to delay explora-

FIG. 3. One week later, there is an encapsulated effusion in the left axilla. Medical boundary is sharply defined and medially convex.

free margin is present, it projects into the lung field with a sharply defined, usually convex or globular, outline. Diagnostic for encapsulation is the appearance of a globular, dense shadow projecting from a peripheral or central attachment into the lung field. Occasionally an encapsulated effusion is so large as to occupy almost the entire lung area so that its shadow is continuous with that of the mediastinum and only a small part of clear lung is seen above or below; the upper or lower level is convex upwardly or downwardly, and in the first instance it would be differentiated from a free effusion by the upward convexity. (See Figs. 2 and 3.)

The most frequent site for fluid encapsulation in infants and children is in the axillary region, either at the base or apex. Physical signs may be confusing, particularly in the presence of coexisting pneumonia. The flat note is suggestive of

tion. The localization of the process is important to the surgeon; it must be borne in mind that variations in technique may so alter the shadows as to cause them to appear larger or smaller, or higher or lower, than they actually are. Fluoroscopy, combined with the lateral and the postero-anterior film examination, should be utilized for exact localization before using the exploratory needle. There may be only one sacculation, or several. The outline of the shadow is sometimes suggestive of multiple locules because of a notching, but more often notching is not present or not to be distinguished. The importance of recognition of multiple encapsulations is paramount to the surgeon who without this knowledge may empty but one loculus leaving others untouched. With spreading infection the adjacent pleurae are stimulated to fibrinoplastic exudation which may be observed roent-

genologically as a band shaped shadow projecting downwards or even upwards from the limit of the encapsulated effusion.

MESIAL EFFUSION

There is a type of encapsulated effusion which Wessler and Jaches call mesial

FIG. 4. Extensive infrapulmonary (diaphragmatic effusion) on right side. The upper border is convex superiorly. There is a slight pleural involvement at apex. Operation.

In this way it comes about that new loculi form and that adjacent ones may contain exudates in varying stages of thickness. In the presence of air, just as in the free effusion, the fluid level is easily seen when the patient is in the erect posture.

CONCEALED OR DEEP EFFUSIONS

The clinical diagnosis of effusions which are hidden or deep and have no point of contact with the costal wall which would simplify the elicitation of physical signs, must rest in greatest part on the roentgen findings for localization as well as recognition. These effusions by virtue of their position in the interlobar fissures, mediastinum, or on the diaphragm inferior to the lung are usually encapsulated. They may be serous or purulent. Roentgenography and roentgenoscopy in the lateral and oblique positions as well as in the anterior and posterior projection are indispensable in these instances.

because it occurs in that portion of the pleural cavity which borders on the heart. It appears as a dense, homogeneous widening of the mediastinum which in the absence of antecedent clinical history might be mistaken for massive adenopathy. Mesial effusion may be primary but is usually secondary to empyema in other parts of the chest.

DIAPHRAGMATIC OR INFRAPULMONARY EFFUSION

Effusions may collect between the pleurae of the lung and the diaphragm and remain localized in this infrapulmonary region. They may also communicate with mediastinal effusions, or parietal ones. When localized, this type of effusion appears as a dense, homogeneous shadow continuous with the heart medially and with the liver when the effusion occurs on the right side. The upper border shows a curve

with the convexity upward. This upward convexity is characteristic of such encapsulation. The effusion may be small or so

mind that the more distant from the screen an object lies the larger will it appear and the greater will be its arc of

FIG. 5. Mediastinal effusion. Large encapsulated effusion encasing left heart. There is some pleural thickening at left base.

large as to extend upward to occupy a large part of the chest. (Fig. 4.)

Such effusions cannot be differentiated roentgenologically from subphrenic abscesses. It is only on operative exploration that the exact relationship to the diaphragm can be determined.

MEDIASTINAL EFFUSION

By mediastinal effusion is meant a collection of fluid between the mediastinal and pulmonary layers of the pleurae, without a communication with the general pleural cavity. Adhesions necessarily exist if the effusion is limited to this location. The effusion is either anterior or posterior, or to the left or right of imaginary planes at the roots of the lungs. It is usually unilateral. The localization is accomplished by means of fluoroscopy or roentgenography in the dorsoventral, ventrodorsal, lateral, and oblique positions, bearing in

rotation. As an illustration, an encapsulation on the left side posteriorly will appear larger in the dorsoventral than in the ventrodorsal position. When in the lateral position the left side is closest to the screen, the area of encapsulation will appear smaller than when the right side is adjacent; at the same time its anterior or posterior position may be determined. On rotation of the patient from side to side, the movement of the sacculation will describe a larger arc when he faces the examiner than when the patient faces the tube. The effusion will vary in roentgenological appearance according to its anterior or posterior position. When it is posterior it is usually band-shaped, vertical and parallel to the spine (Savvy, Assman). Its breadth will be modified directly by the amount of fluid present. In the anterior position it takes on a triangular outline with the hypotenuse straight or convex,

facing laterally, the base on the diaphragm, and the other side adjacent to the spine. The shadow is dense and homogeneous.

ance of double contour of the heart from which an effusion must be differentiated. They are: collapse of the lower lobe, retro-

FIG. 6. Lateral view showing multiple areas of lung suppuration with which are associated in interlobar fissures outlining middle lobe.

When there is an effusion in the region of the sinus, where reflection of the mediastinal pleura to the costal wall takes place, together with an effusion in the mediastinum, a costomediastinal effusion is seen (Herrenheiser). Such an effusion posteriorly creates the appearance of an anterior mediastinal effusion, that is, a triangular shadow whose hypotenuses face laterally. Effusions in the posterior mediastinal space are frequently costomediastinal. (Fig. 5.)

When the effusion is marked the shadow may extend beyond the limits of the cardiac density; when moderate or small it lies concealed behind it, particularly on the left side. It is in this way that a double contour of the heart is formed. The summation of both the fluid and the heart densities causes an increased opacity in the region of the effusion. There are other conditions which produce an appear-

cardiac pneumonia, bronchiectasis, Pott's abscess, and adenitis situated posterior to the heart.

Pneumonias, like effusions, are homogeneously dense but their limitations are not as a rule so sharply defined unless there is an interlobar demarcation which in this location would not occur. Pneumonias in regions which come into differential consideration do not appear band-shaped; and, if triangular, the border is not so straight, sharply defined or convex as in the effusions.

Collapse of the lower lobe is roentgenologically similar to an effusion of the anterior mediastinum or to a posterior effusion which is costomediastinal. Here the clinical course and history must aid the differentiation. With collapse, there is always a compensatory emphysema of the upper lobe.

Bronchiectasis may be located in the lower lobes posteriorly and medially. With

it there may be collapse of the diseased lobe, the x-ray appearance of which resembles mediastinal or costomediastinal

Massive swelling of lymph nodes behind the heart, the bifurcation nodes, may be pronounced enough to create a more or less

FIG. 7. Communicating pleural effusion between costal pleura and interlobar fissure between right upper and middle lobes.

effusions. An irregular, honey-comb-like shadow or multiple dilatations may be roentgenologically so evident as to immediately indicate the nature of the process. It is sometimes necessary, however, to introduce some contrast-producing substances, such as iodized oil, to outline the dilatations. The clinical history and signs of bronchiectasis, either in the presence or absence of characteristic dilatations, aid the differentiation from effusions of the mediastinum.

In Pott's disease, the abscess may be unilateral and its lower part located in or adjacent to the mediastinum, so that the x-ray appearance may simulate mediastinal effusion. The vertebral column must be examined for a focus or a suggestive narrowing of the intervertebral discs. Pott's abscesses are usually bilateral, not necessarily symmetrically so, more or less elliptical, and associated with manifest disease of the vertebrae.

triangular dense shadow whose lateral margins, however, are usually rounded and perhaps notched, suggesting lymphadenopathy. The swelling is usually bilateral.

INTERLOBAR PLEURISY

For the understanding of pleural effusion in the interlobar fissures a visualization of the anatomy of the interlobar fissures is necessary. The lung is as a rule divided by interlobar fissures into an upper, a middle and a lower lobe on the right side and an upper and a lower one on the left. There is, then, a large interlobar fissure on either side separating the upper from the lower lobes and in addition a small one on the right side between the upper and middle lobes. The middle lobe is bounded inferiorly by the lower part of the large fissure. While this is the usual division the presence of aberrant or incompletely separated lobes is not uncommon.

Recently the azygos lobe has been

described roentgenologically and confirmed at autopsy by Wessler and Jaches, Bendick and Wessler, and Stoloff. It is more com-

with the superior vena cava. The azygos lobe is subject to the same pathological processes as the other lobes.

FIG. 8. Homogeneous shadow near right cardiac margin at base, the nature of which suggests infiltration. Left ventricle is enlarged.

monly outlined in the roentgenograms of children than in adults. This lobe is caused by a persistence of the fetal position of the azygos vein which lies lateral to the spine. In its passage from the posterior chest wall to its point of entrance into the superior vena cava the azygos vein traverses the tissue of the right upper lobe. Accompanying it is a reflection of the parietal pleura which occupies the azygos fissure between the azygos lobe and the rest of the right upper lobe. The fissure is outlined by a faint linear shadow, coursing from the apex, either at its midpoint or more medially or laterally, downwards with an outward convexity which varies in depth, to the level of the second costal cartilage where it terminates in a dense button-like, spindle- or comma-shaped shadow about the size of a pea which represents the confluence of the azygos vein

TOPOGRAPHY OF THE FISSURES

Left Interlobar Fissure. This consists of a line beginning 6 to 8 cm. below the apex at about the level of the third dorsal vertebra, extending from the posterior margin of the medial surface of the lung, backward and slightly upward to the posterior surface, then arching slightly over the posterior convexity and downward, it crosses the fourth interspace in the mid-axillary line, and extends to the level of the sixth costal cartilage, cutting the lung above the cardiac incisure. Thus it makes of the inferior part of the lower lobe what was called by Luschka a tongue-shaped process of lung, which is now known as the lingula. This represents the external markings of the left or great interlobar fissure; the diaphragmatic and mediastinal markings were not portrayed until Fleischner adequately

described them. If the line described in the foregoing is continued dorsally and medially on the diaphragmatic surface

liquely, posteriorly and medially toward the lower part of the hilum. The lung tissue lying anteriorly and medially (the

FIG. 9. Roentgenogram in lordotic position reveals effusion in lower part of large interlobar fissure adjacent to mediastinum, evidenced by triangular shadow protruding laterally.

toward the lower medial margin of the lung below the hilum, then extended, slightly dorsally, upward to the hilum, and from above it steeply to the level of the third dorsal vertebra, the diaphragmatic and mediastinal markings are now completed. Because of the predominantly left-sided position of the heart, only a narrow part of the upper lobe has a diaphragmatic surface.

The right side differs from the left as follows: Right Interlobar Fissure: A line starting at the level of the third dorsal vertebra and extends posteriorly to the posterior convexity of the lung, over which it then arches with a convexity less marked than on the left side, and begins its descent toward the axilla on a less steep incline. The diaphragmatic surface is reached in the anterior or mid-axillary lines, or between the two; from there it takes its course on the diaphragm ob-

middle lobe) thus comprises one-fourth of the diaphragmatic surface. The mediastinal course is similar to that of the left side. The fissure between the upper and middle lobes of the right side is represented by a line practically horizontal at the level of the fourth rib, extending laterally to the great fissure.

If the great fissures are projected on a flat surface, a propeller-like figure (Dietlen) is produced. They may be visualized as oval surfaces which are not plane, lying at an angle of 45° with the bases of the lungs and which have been twisted on themselves with the hilum as a fulcrum, so that the upper half faces forward and slightly laterally and the lower half faces forward and somewhat medially. The medial boundaries of the great fissures are less oblique than the lateral ones. The small fissure on the right side, called dome-shaped by Fleischner, which is in-

clined laterally more than anteriorly, has an upward convexity which is more marked dorsoventrally than mediolaterally. Since the fissures vary in depth the lobes may be connected by only a pleural bridge or a small pulmonary pedicle or they may be practically continuous with each other save for a superficial fissure. The pleurae are best thought of as sacs which are so invaginated by the lung that the interlobar as well as the costal, diaphragmatic and mediastinal surfaces, except in the root area for entrance of the vessels and bronchi, are completely covered by a continuous serous membrane which is always in close apposition with another pleural surface.

ROENTGEN DIAGNOSIS

Owing to the oblique position of the great interlobar fissure the upper lobe is really in a sense anterior, as is also the middle lobe; the lower lobes are posterior. If there is a small effusion or a thickening of the pleurae in the large slit and the x-ray tube is focussed in the customary position upon the upper dorsal vertebrae, the rays may penetrate through it so that there will be no shadow or at best only a very faint one, for the fissure is narrow and there is an attenuation or subtraction of shadow density by the adjacent aerated lung. The impression on the film or screen will be faint, hazy and not definitely circumscribed. With increasing amounts of effusion or thickening the density increases but it is usually not sharply outlined. Such processes are most commonly located medially and contiguous to the mediastinum, for an interlobar mediastinal pleurisy is frequently present. The density extends from the root of the lung laterally. The shadow is homogeneous and infiltrative processes are suspected.

If a lateral exposure be made the true nature of the pathology becomes apparent. Great penetration must be used in order to differentiate it from the cardiac density. Dependent upon its location (upper, middle

or lower part of the fissure) its length will vary and the amount of exudation or fibrous thickening will determine its thickness. If the involvement be in the upper part, it is seen in the lateral examination as linear or as a band-shaped shadow; or, if there is effusion, it appears as an oval, globular, or elliptical shadow, dependent on the amount of fluid and separation of the pleural surfaces from each other (Fig. 6). This is also true in the lower parts of the fissures. When there is little or no adhesion of the apposing surfaces the fluid content gravitates to the diaphragm and a more or less triangular shadow is produced which rests on the diaphragm and courses obliquely upward and backward.

In the posteror anterior position the exact nature of the involvement may come to light if the fissure is so placed that its greatest length or depth will be horizontal to and traversed by the central rays of the tube. In this manner a summation of shadows is effected and a definite sharply circumscribed shadow is cast. This position may be attained in one of two ways: (1) The lordotic position, first utilized by Fleischner, then by Wimberger, Rach, Stoloff, in which the patient is made to assume extreme lordosis by protrusion of the abdomen while the shoulders are held back; (2) elevation of the tube to a high point, with downward tilting, while the film is relatively low in position (Stoloff). In infants the first technic must be used by holding the patient in lordosis. Older children easily imitate the position after it is demonstrated. The first is the technic of choice.

In roentgenograms made in either manner a shadow appears which is band-like, globular, oval or triangular, and which is sharply circumscribed above and below, standing out clearly in the lung field, and occurring in any part of the fissure. It is usually medial. When there is an associated involvement of the mediastinal pleurae, as is quite frequent, a triangular pennant-like density projects from the

cardiac opacity laterally into the lung field. This is characteristic of a mediastinal-interlobar pleuritis (Fleischner), although it occasionally occurs in the absence of associated mediastinal pleural disease (Figs. 7 and 8). Small effusions cannot be differentiated from thickenings (Fig. 6). As the fluid accumulation increases its nature becomes recognizable, for thickenings do not attain such size nor do they have configurations such as globules or ovals. When the fissure between the middle and the upper lobes is attacked this involvement is easily recognized in the usual dorsoventral position, for the ray in passing through its entire depth the fissure being more or less horizontal, brings about a piling up of the shadow. The roentgenographic image appears as a hairline or a band if thickening or slight effusion is present, or as an ellipse if a larger effusion is contained. Since the fissure is dome-shaped, sometimes more accentuated than at other times, it may have, in a sense, two levels. For this reason two parallel hairline shadows are occasionally seen (Schoenfeld). When mediastinal pleuritis is associated with middle-fissure disease a sudden widening may extend into the cardia, producing the appearance of mediastinal interlobar pleurisy as already described, but the latter is seen in the large fissures only in lordosis.

Several pleural surfaces or combinations of them may be simultaneously affected so that communicating shadows are distributed through a lung field. Thus, there may be a well-defined shadow of effusion in the uppermost part of the fissure separating the upper and lower lobes, continuous with a band-like shadow over the lung indicating free effusion (Fig. 9). On examination in the lordotic position, the lung field may reveal an additional effusion in the lower parts of the great interlobar fissure.

Interlobar pleurisy in children is not uncommon. The most frequent cause is tuberculosis, arising in one of the following ways: the primary focus is adjacent to

the interlobar pleura, or a primary or secondary infiltration lies contiguous to it, or there is a pleural reaction caused by the proximity of the mediastinal limits of the fissures to the diseased regional lymphnodes. At times there are communicating nodes which are actually present within the limits of the fissures, exerting a direct effect on the pleura.

Other causes of interlobar pleurisy are non-tuberculous pneumonias and cardiac decompensation. These are far less frequent.

CHRONIC DISEASE OF THE PLEURAE

After the resolution of a pneumonic infiltration, a fine hairline or narrow band-like shadow may be seen adjacent to the lateral costal wall, caused by a fibrosis, the sequel to an infiltration. This may gradually disappear or persist for a long time. Such thickenings are frequently seen in the interlobar fissures as well as on the pleurae of the mediastinum. They may follow healed empyemas, tuberculous effusions and dry pleurisies. Where the thickening affects the whole or a part of only one surface, a shadow appears as a homogeneous veiling overlying the involved part. If the lateral parts are free of pleural disease, the customary band-like axillary thickening is not present. Fibrous adhesions between the pleurae and the diaphragm or mediastinum frequently follow in the wake of pulmonary inflammation. Their presence may not be seen but it is suggested from the impairment of movement of the diaphragm or the mediastinum, when the patient is studied fluoroscopically. They are more frequent in older children than in infants. The larger adhesions cast string-like, band-like shadows, or tiny pyramidal projections on the attached part.

Occasionally there is a persistent chronic massive thickening of the pleurae which is seen as a dense homogeneous shadow obliterating the whole or a part of the lung field, and by fibrous adhesions contracting the entire thoracic part. Atelec-

tasis of the underlying lung may be present. The ultimate appearance may resemble that of a massive atelectasis of the lung, with mediastinal displacement and diaphragmatic elevation towards the affected side. The differentiation will rest upon the clinical history and course, with particular consideration of the history of operation or foreign body aspiration.

There are two shadow-casting conditions in infancy and childhood which must be eliminated as confusing factors likely to lead to an erroneous diagnosis of pleural thickening or exudation. The first is the position of the scapula, the inner margin of which may overlap the periphery of the lung, casting a linear shadow parallel to the outer boundary of the thorax. Demonstration of its continuity with the

rest of the scapula will readily differentiate this shadow from a pleural thickening. The second condition is seen in some infants where the ribs at the sternal junctions undergo rachitic widening of the epiphyses, at times so marked that the shadows are continuous one with the other creating an appearance of a ribbon-shaped shadow adjacent to the lateral thoracic wall, simulating pleural thickening or exudation. Close examination, however, will show evidence of rickets, and the clinical history and signs will definitely eliminate pleural disease. In addition a pleural thickening as wide as the shadow cast by a rachitic rosary is usually denser, sharper, more smoothly defined and does not show the multiple medial convexities which outline the epiphyses.

The American Journal of Surgery is truly independent and enters into no "entangling alliances." It publishes many papers that were read before the leading surgical societies of the Country, but, it is *not* the "the official organ" of any organization. Every manuscript is selected by the editors, as worthy of publication—nothing is published merely because "it was read at the meeting."

EDITORIALS

ABORTION AND CONTRACEPTION

FOR INDICATIONS OTHER THAN PURELY MEDICAL

WHEN J. Whitridge Williams, in July 1928, addressed the University of Washington on Indications for Therapeutic Sterilization in Obstetrics,¹ he invited the criticism of his colleagues. In clear straightforward fashion, many of his cases were presented, "so that the justifiability of the course pursued can be criticized." Up to now no one, to our knowledge, has reviewed his opinions, either to approve or to take issue with them.

In a group of 118 women sterilized at his clinic, there were 15 sterilized for mental or psychiatric conditions, and 4 for social indications. Although he has rejected many cases sent to him, because

they do violence to his conscience, he is clear on these. In the rest of the group, and here he believes that few will take serious exception, there are 45 cases sterilized by hysterectomy, or hysterotomy with exsection of the proximal end of the tube, *prior to viability of the child*. This gives him no concern, but he is not at all sure that his procedure in the first 19 cases will meet with general approval. Yet I am disturbed, because, in a specialized obstetrical experience covering many years in two large hospitals, I have not found it necessary to abort or sterilize anyone.

He discussed contraception as well, and,

like him, I find abortion, sterilization and contraception so intimately related, as to make individual treatment from a medical point of view difficult. Abortion is but a by-product of sterilization in many of his cases, and, at best, sterilization is but contraceptive treatment made reasonably certain.

Reviewing his cases briefly, we find 4 cases of pronounced feeble-mindedness, 4 cases of dementia precox, 2 cases of frank psychosis, 1 case of chorea and repeated puerperal insanity, and 1 case of postencephalic depression. Seven of these patients were sterilized during pregnancy, prior to viability of the child.

As to the four social indications. One girl of eighteen with a contracted pelvis, syphilis, tuberculosis and general worthlessness was sterilized at cesarean section in her first pregnancy. Another with 2 microcephalic children had abdominal hysterotomy and sterilization in her third month. A girl of twenty, mental age twelve, was sterilized at her second cesarean section; while the fourth, age twenty-seven who had undergone two cesarean sections and four spontaneous deliveries, was sterilized because she was losing ground physically, had a worthless husband, and could not keep a position if she were constantly pregnant.

Sterilization is widely practiced, with and without much thought on the part of the operator, but often because he is influenced by the desire of the patient or by the pitiful story she tells. In a recent survey of 1805 cases of cesarean section made by the Brooklyn Gynecological Society,² sterilization was done in 59 out of 834 cases of contracted pelvis, and in but 16 out of 130 cases of repeated cesarean sections.

Abortion may or may not be the material corollary of contraceptive failure, but apparently it often is. Contraceptive advice is widely given, when, in the physician's opinion, pregnancy would jeopardize life, or even health, through the operation of social or economic factors over which

the physician or the patient have no control. I do not contend that the physician should be prepared to induce abortion, if failure follows his instructions. Not at all. It may be though that there is no middle ground; one may follow the other. Many, however, give birth control information for reasons for which they would shrink from inducing abortion.

But even medical indications are not universally accepted and wide divergence of views exist. We have no one mind upon this important subject. There are 29 birth control clinics in the United States. Let us look at the report of one of them, one which we would expect to be the most conservative. In the First Report of the Bureau of Contraceptive Advice in Baltimore,³ J. Whitridge Williams analyzed 168 histories of those who had been given advice, and divided them into 4 groups.

In the first group of 70, there were 38 cases in which the indications were tuberculosis, kidney and organic heart disease. There were 14 nervous disorders listed as psychoneurosis, morons, dementia precox, and 1 patient whose husband had a mental affection. The remaining cases comprised syphilis, thyroid disease, epilepsy in the wife or husband, recent operations, fracture of pelvis, encephalitis in the husband, spina bifida, chronic asthma, breast lesion, acute gonorrhoea, and hypertension with difficult labor. A wide and varied assortment of "those presenting definite medical indications." Williams says that in nearly every instance, the indication for advice seemed thoroughly sound.

In the second group of 23, advice was given to those who complained of too frequent pregnancies, with complications listed as undernourished (2), anemia (4), general debility (3), asthenia (3), 15 miscarriages (1), running down (2), husband drunken (1), syphilis (1) and debility (6). Here Williams states that advice was justifiable both from the medical and humanitarian point of view.

The third group Williams admits is

more debatable. Sixty women had an excessive number of pregnancies within a comparatively short space of time. Here the income of the husband was held to be an important factor.

In the fourth group, the historical data were not sufficient for judgment, but Williams feels that he would have agreed had he seen the patients.

That contraceptive advice and treatment may be given as a matter of right, many will deny; but that it is common practice no one will dispute. That medical indications are far flung, this report bears solemn witness. We give advice for run-down conditions and general debility. If general housework were included, no one need have a baby.

There are, however, certain vague but widely accepted indications for abortion. It is easy enough to enumerate medical conditions, but I am sure that clinically the patient is more than a case record. Even those who would agree upon fixed indications, would probably disagree in the management of their cases. Hard and fast lines may not be drawn.

Once we felt that abortion was lawful only if life itself were threatened by continuation of pregnancy, but now serious or even possible damage to health constitutes a valid reason for interference. The child itself apparently is not considered.

There is general agreement that severe kidney lesions call for active intervention. If albuminuric retinitis is a positive indication, hypertension and edema certainly are not. There is much evidence to show that continued pregnancy results in further kidney damage, yet conscientious effort should be made to carry the child to viability.

The case for tuberculosis is not so convincing. In active cases, the risk certainly increases. Parturition, it is said, fans latent lesions to a flame, but there is absolutely no proof that early interference would prevent exacerbations, or that abortion may not be as harmful in its effects as labor itself. In arrested cases,

I believe it does more harm than good. The chief argument against pregnancy is that it is apt to bring about forgetfulness of the lesion and neglect of treatment. But there is no excuse for that.

In heart disease, mitral stenosis or otherwise, early abortion is based upon pure speculation. Broken compensation is not due to the pregnancy, unless the uterus is of sufficient size to cause circulatory embarrassment, a distress due to mechanical factors. Viability should always be awaited and cesarean section considered. Recent advance in the technique of local anesthesia, and the increasing safety of spinal, strengthen this position.

With all this we should be deeply concerned, for there is a changing point of view in the medical profession. Social, economic and eugenic reasons move us deeply. The ethical standards of the public are lower than ever, and the physician has become less and less able to withstand the pressure brought to bear upon him. Medical indications are apt to be loosely accepted at their face value, and a multitude of other reasons find steadily increasing favor with us. Times have changed, and we with them.

Modern life steadily diminishes women's capacity for childbearing. Husbands meet increasing economic stress less willingly. A safer technique and emolument has swelled the ranks of the criminal abortionists. Women are aware of our slackened conscience. Their friends have found honest doctors more sympathetic, more acquiescent, not so deaf as they once were. A little emphasis on this or that point, and her cause is as just as the next one, a vicious circle.

Common sense and thinking for ourselves has brushed aside old religious deterrents. Common contraceptive knowledge has shaken and weakened our moral fibre. Birth control propaganda grows more ardent. We are advised to space our children, to leave little or nothing to nature. "The patient may be advised to make the insertion of the pessary a part

of her evening toilet if desired, so as to be always prepared . . . [it] made a part of the daily routine of undressing." Dilatation, rupture or snipping the hymen to fit a pessary is recommended. "If this procedure were adopted by all young women before marriage, it would save considerable embarrassment and sometimes much pain."⁴ "It was the last straw," says another, who possibly inherited his contraceptive beliefs. "I have a very distinct memory, dating from my seventh year, of my discovery of a paper covered book on contraception, carefully hidden away in the top drawer of my mother's wardrobe, and an irreverent member of the family once referred to me as an "accident." So I can only suppose that some attempts at contraception had been made, though of their nature, duration and regularity, I have no exact knowledge."⁵ Nothing is sacred. Not even our mothers.

Perhaps we go too far. If adequate reasons for contraception include general debility, general malaise may be added. There was a time, however, when abdominal sterilization, and deliberate destruction of the fetus, not because its presence jeopardized life or even health, but because its eugenic outlook was poor, would be considered a crime akin to infanticide. Perhaps it is.

Fairbairn⁶ believes that none other than purely medical considerations should be allowed to influence us. Once other than purely medical factors are allowed to count, no line can be drawn between therapeutic and criminal abortion. "Nothing is worse than the mental torture of

illicit pregnancy," he says. "Are we then justified in terminating these?"

Ethics and morals are not a religious matter. Men may decide upon a basis of morality, it is true, but our conscience is founded upon and guided by something deeper than that. We do not have to invoke divine revelation. Rather do we depend upon the unchanging law of good and evil which is binding upon all of us, and finds its expression in all sorts of principles with which we are constantly in contact. The physician is not the dispenser of life and death. He is not the arbiter of the universe. Individual cases may evoke his pity and wring his heart, but he should feel no call to redress all the wrongs and cure all the wrongs and cure all the ills of society. That would keep us very busy.

To the question, "Have we the right to interfere with a normal pregnancy?" My answer is "No."

CHARLES A. GORDON, M.D., F.A.C.S.

[The author has made out an excellent case against birth-control and the interference of a normal pregnancy. We will be glad to receive other comments on these subjects. Ed.]

RADIOLOGICAL DETECTION OF ABDOMINAL ADHESIONS

WE frequently hear it said that the x-ray "failed to show" abdominal adhesions. Pleural adhesions, thanks to the surrounding medium of air in the lungs or in the pleural cavity, can be shown very satisfactorily but

abdominal adhesions are non-opaque to the x-ray.

The detection of intraabdominal adhesions is dependent upon certain circumstances, some of which are under the control of the radiologist: first, the ad-

hesions must fix or seriously limit the excursion of a normally movable, visualizable organ; or, second, in the case of the gastrointestinal tube the adhesions must interfere with the normal onward progress of the visualized contents of the viscus; or, third, pushing or traction by the protected hand or a wooden spoon under the fluoroscopic screen may move some structure so that adhesions may be reasonably inferred from a simultaneous movement of another structure to a demonstrable degree; or, fourth, pneumoperitoneum may be established and the adhesions actually seen.

It is well known that loose intestinal adhesions, even though involving numerous coils of small intestine, often result in no appreciable harm and cause no recognizable mechanical or functional disturbance. The adhesions which really cause trouble are those which by obstruction interfere with the motor mechanism or with the mobility of the bowel, or by traction cause pain. If the adhesions do none of these things (and many cases fall under this heading), then it will be practically impossible to visualize them by any x-ray maneuver except artificial pneumoperitoneum, and this is a major procedure to which many surgeons prefer an exploratory laparotomy. When any such radiologically undemonstrable adhesions are found at operation, the surgeon is very apt to remark that the x-ray did not show them, and to leave an impression that the x-rays are often undependable.

One does not ordinarily see stars in

daylight. The x-ray cannot be expected to do unreasonable things. It is a physical means which strictly follows physical laws. It is quite possible for adhesions to be present even between a normally movable organ and some fixed point without detection on x-ray examination, because at that particular moment the adhesions may not be producing any degree of obstruction. Such a patient examined again during one of his periodical abdominal attacks may show the typical x-ray signs of mechanical obstruction.

Therefore, when x-ray help is desired in the detection or localization of disturbing adhesions within the abdomen, the radiologist should be acquainted in detail with the problem and he should carry out his examination at such frequent intervals that he may discover even minor aberrations of motor behavior, and watch for a chance to examine in an acute attack. He must carefully manipulate under the screen during deep inspiration and deep expiration, and he must employ change of position and traction or pushing upon the scar or the abdominal wall. Further information may be deduced from a comparison of the films recorded at different times during the examination, noting the relative position of some definite loop of bowel under different circumstances.

In the face of a negative report following such carefully performed examination, adhesions may, of course, be present, but it is extremely doubtful if such adhesions will be helped by any surgical procedure.

List of operations in New York hospitals on file in our office daily.

"DUPUYTREN'S CONTRACTION"

GUILLAUME BARON DUPUYTREN was a character of varied facets. He was the first surgeon to do so many things; he was the most popular teacher of his day; he was honored as are few physicians; he had no friends; he left his wife and only loved his daughter; he was arrogant, sarcastic, envious of the success of others, had "a brutal lack of consideration for the patients entrusted to his care," and was dubbed by Lisfranc, "the brigand of the Hôtel Dieu."

He was born October 5, 1777 or 1778 at Pierre-Buffière, a small town of Haute Vienne, near Limoges.

In 1789 a cavalry officer, with the permission of Guillaume's father, sent the boy to school in Paris. He attended classes for four years. Due to the effects of the Revolution the school closed. He was determined to complete his studies and at a great sacrifice, enduring true hardship, he finally reached his goal.

When about eighteen he was appointed prosector in anatomy in one of the schools established by Fourcroy.

In 1801 he was made head of his department with the title, *chef des travaux anatomiques*. Among his pupils were Laënnec and Cruveilhier.

In 1804 he successfully competed against Roux and others for the position of surgeon of the second class at the Hôtel Dieu. In time he was the surgeon-in-chief.

In 1812, after a brilliant rise, he was appointed to the chair of operative medicine as successor to Sabatier.

Dupuytren had but one hobby and passion—work. He arose daily at five and began his ward work at six. After morning rounds he gave his clinical lec-

tures in the amphitheater, followed by operations, work in the out-patient division and post-mortem examinations. This finished the morning. During the afternoon he attended to his large consulting practice. In the evening he again made hospital rounds and frequently performed from one to three operations.

This routine year after year was too much for his body. One day while walking to the hospital he was taken with a slight stroke of apoplexy. He recovered and went on a tour of Italy, his first vacation. On his return he tried to carry on his old routine but his health failing he had to relinquish his place at the hospital.

Dupuytren was the first surgeon of his time and the founder of clinical surgery in France. He was the first to demonstrate the nature of yellow elastic and erectile tissue. He proved by animal experimentation that the spleen can be surgically removed with comparative safety. He taught that chronic enlargement of the testis is due to lues. He introduced greatly improved methods of treating fractures. We read he was the first to excise a carcinomatous cervix and the first to describe congenital dislocation of the hip. He changed the current treatment of urethral stricture, using flexible bougies. To this day his name is associated with idiopathic contraction of the palmar fascia, Dupuytren's contraction (1832). He wrote little. As a teacher he was famous.

He was a member of the Institute, a member of the Academy of Medicine and its president in 1824. In 1820 Louis XVIII conferred a baronetcy on him. He was surgeon to Louis XVIII and Charles X.

He died on February 8, 1835.

GUILLAUME DUPUYTREN

[1777-1835]

BIOGRAPHICAL BRIEFVITIES
"Dupuytren's Contraction"

The American Journal of Surgery
N. S. Vol. VIII, March, 1930

[From Fernelius' *Universa Medicina*, Geneva, 1679.]

BOOKSHELF BROWSING

OLIVER WENDELL HOLMES*

PHYSICIAN, POET, AUTHOR

FREDERICK C. WARNSHUIS, M.D.

GRAND RAPIDS, MICH.

THERE is a common complaint against the biographies of men, that they are, with few exceptions, insufferably dry reading. The cause is simple in that, if a man has put the best of himself in his work, he has as a rule left little for another to tell. "There are but two people who can tell the story of a man's or woman's life, one is the person himself, and the other is the recording angel." Having no relationship or communication with the latter I may fail in my endeavor to interest you, but when we also recall that Dr. Holmes has written so freely about himself, in the end this paper may possibly become of interest.

An interest in the biography of medical men, as a pastime, has convinced me of its value as an educational factor. In the study of the biographies of the lives of some of the leaders in our profession, I have been impressed that the Hippocratic ideals are realized and exemplified in their lives. If, therefore, those teachers can enlighten us as to the darkness that went before, and the darkness that is to follow, let us hear what they have to teach us, and though we may not as yet perceive any special line of research, we may hold that every addition to our knowledge is

one small step towards the great revelation. But let us proceed without further effusion.

Oliver Wendell Holmes, the son of Rev. Abiel Holmes, a clergyman of the Church of England, was born in Cambridge August 29, 1809. There is little of importance to record of his childhood, suffice it to state that at 15 he entered Philips Academy in Andover. Staying but a year in this institution he matriculated in Harvard in 1825, graduating with what is now known as the "Famous Class of Twenty-Nine." Contemplating the legal profession as his field of work, he studied law for one year in the Dane Law School. In answering the question as to why he relinquished the study of law to enter that of medicine, I can best do so by quoting his words:

What determined me to give up law and apply myself to medicine I can hardly say, but I had from the first looked upon that year's study as an experiment. At any rate I made the change, and soon found myself introduced to new scenes and new companionships.

So from law Holmes turned to medicine. He says in his reminiscences:

At the end of the first year in the Dane Law

* Submitted for publication September 25, 1929.

School, I took up my new study which was to be my final choice. There is something very solemn and depressing about the first entrance upon the study of medicine. The white faces of the sick that fill the long row of beds in the hospital wards saddened me and produced a feeling of awe-stricken sympathy. The dreadful scenes in the operating theatre, for this was before the days of ether, were a great shock to my sensibilities, though I did not faint as students occasionally do. When I first entered the room where students were seated at a table with a skeleton hanging over it, and bones lying about, I was deeply impressed, and more disposed to moralize upon mortality than to take up the task of osteology which lay before me. It took but a short time to wear off this earliest impression. I had my way in the world to make and meant to follow it faithfully. I soon found an interest in matters which at the outset seemed uninviting and repulsive, and after the first difficulties and repugnance were overcome I began to enjoy my new acquisition and knowledge. The head of the private school at which I studied was Dr. James Jackson, a very wise and a very good man, whose influence on the minds of his students who followed him in his visits to the hospital, and who listened to his teachings, was of the soundest and best character. Dr. Jackson never talked of curing a patient except in its true etymological sense of taking care of him. I think we may say in general that the doctor who talks of curing his patients belongs to that class of practitioners known in our common speech as "Quacks." It is in medicine as in surgery—nature heals; art helps, if she can, sometimes hinders, with the best of intentions; oftener is entirely ignored by the great remedial agencies, ordained by the shaping intelligence, which gives form and life to mortal organization.

Holmes attended two courses of lectures in this private school. If he was to be anything better than a rural dispenser of pills and powders he had to pass, at the very least, two years in European hospitals. Practically this must have been incorporated in the program when his choice of the medical profession was made. Yet so large a part of the "Consideration" received by clergymen was "good," rather than "valuable," that this foreign

education would have been wholly impossible, had it not so happened that the daughter of a prosperous Boston merchant had brought with her into the clerical household a purse not altogether empty; and even with this aid, it would seem that some effort had to be made in order to send the young student to Paris with funds enough in his pocket to enable him to live comfortably, "like a gentleman," as he jealously expressed it. But his father and mother, like true New England parents of that day, came gallantly to the mark and equipped him.

More than once in his writings Holmes refers to his delightful student days in France where he was the follower of the great Louis. His valedictory address to his class in 1882 is largely made up of his reminiscences of his old Paris teachers. The following are his interesting comments on Lisfranc and Ricord.

Of Lisfranc, I can say little more than that he was a great drawer of blood and hewer of members. I remember his ordering a wholesale bleeding of his patients, right and left, one morning when a phlebotomizing fit was on him. I recollect his regretting the splendid guardsmen of the old Empire, *for what?*—because they had such magnificent limbs to amputate. I got along as far as that with him when I ceased to be a follower of Lisfranc.

Speaking of Ricord, Holmes says:

There was also the "Vivacious Ricord," whom I remember calling the Voltaire of Pelvic Literature, a skeptic of the morality of the race in general, who would have submitted Diana to treatment with his mineral specifics and ordered a course of blue pills for the vestal virgins.

Late in November of 1835 he returned to Boston and commenced the practice of his profession in January, 1836. In 1847, he was appointed Parkman professor of anatomy in Harvard, which chair he held for thirty-five years.

As the story of his life goes on it is now that he commences to attract the attention of his friends, and inspires by his life

the enduring reverence of posterity. Follow me while I lead you, somewhat hurriedly, through the succeeding years by portraying him in the rôle of *Anatomist*, and medical *Essayist* with an occasional citation of incidents that reveals the broadness of his character and mind.

ANATOMIST

That Holmes should have selected anatomy and dissection as his province of labor may seem a little odd when we are told that he was too tender hearted to practice medicine. Here is what two good witnesses, who have been placed upon the stand, deponeth to his point. Dr. Cheever says:

Too sympathetic to practice medicine, he soon abandoned the art for the science, and always manifested the same abhorrence for death and tenderness for animals. When it became necessary to have a freshly killed rabbit for his lectures, he always ran out of the room, left me to chloroform it, and besought me to not let it squeak.

Professor Dwight says:

In spite of the attention bestowed on dissection, I do not fancy that he much fancied dissecting, though the museum still has some few specimens of his preparation. Once he asked me what part of anatomy I liked best, and on my saying the bones, he replied, "So do I; it's the cleanest."

To better present to you Dr. Holmes in the rôle of anatomist permit me to describe one of his lecture hours. It nears one o'clock, and the work in the demonstrators' room in the old Medical school in North Grove Street becomes even more hurried and eager as the lecture hour in anatomy approaches. Four hours of busy dissection have unveiled a portion of the human frame, insensate and stark on the demonstrating table. Muscles, nerves, and blood vessels unfold themselves in unvarying harmony, if seeming disorder, and the subject is nearly ready to illustrate the lecture. The room is thick with tobacco smoke. The winter light, snowy and dull,

enters through one tall window, bare of curtains, and falls upon a lead floor. The surroundings are singularly bare of ornament or comfort or beauty, and there is naught to inspire the intellect or imagination, except the marvelous mechanism of the poor dead body which lies dissected before us, like some complex and delicate machinery whose uses we seek to know. To *such* a scene enters the *poet*, the *writer*, the *wit*, Oliver Wendell Holmes. Few readers of his prose or poetry could dream of him as here, in this carnal house, in the presence of death. The very long and steep flight of stairs leading up from the street below resounds with a *double* and labored tread, the door opens and a small, gentle, smiling man appears, supported by the janitor, who has often been called to help him up the stairs. Entering, and giving a breathless greeting, he sinks upon a stool and strives to recover his asthmatic breath. Anon, recovering, he brightens up and asks, "What have you for me today?" and plunges, knife in hand, into the depths of his subject. Time flies, and a boisterous crowd of "turbulent Bob Sawyers" pours through the hall to his lecture room door and begin a rhythmical stamping and shouting and pounding. The doors open, a rush takes place, some collapse, some are thrown headlong and three hundred raw students precipitate themselves into a bare and comfortless amphitheatre. Meanwhile the Professor has been running about, now as nimble as a cat, selecting plates, rummaging dusty museums for specimens, arranging microscopes and displaying bones. The subject is carried in on a board; no automatic appliances, no wheels with pneumatic tires, no elevators in those days. The cadaver is decorously disposed on a revolving table, and is always covered with a clean white sheet. Respect for pure humanity and admiration for God's divinest work is the first lesson and uppermost in the poet-lecturer's mind. He enters and is greeted with a shout and stamp of applause. Then silence and there begins a

charming hour of description, analysis, simile and anecdote, which clothes the dry bones with poetic imagery, enlivens a hard and fatiguing day with humor, and brightens to the tired listeners the details of a difficult, though interesting, study. We may say tired listener because the student is now listening to his fifth consecutive lecture that day, beginning at nine o'clock and ending at two. No rest, no recovery for the dazed senses, which have tried to absorb materia medica, chemistry, practice and obstetrics all in one morning. One o'clock was always assigned to Dr. Holmes because he alone could hold his exhausted audience's attention. He came in with a grave countenance. His shoulders were thrown back and his face bent down. No one realized better than he that he had no easy task before him. He had to teach a branch repulsive to some, difficult to all; and he had to teach it to a jaded class which was unfit to be taught anything. The wooden seats were hard, the backs straight and the air bad. The effect of the last was alluded to by Dr. Holmes in his address at the opening of the new school in 1883, in which he referred to those early days as follows:

So when the class I was lecturing to was sitting in an atmosphere once breathed already, after I had seen head after head gently declining and one pair of eyes after another emptying themselves of intelligence, I have said inaudibly, "Sleep on dear youth, this does not mean that you are indolent or that I am dull; it is the partial coma of commencing asphyxia."

To make head against these odds he did his utmost to adopt a sprightly manner and let no opportunity for a jest escape him. These would be received by quite appreciation by the lower benches, and with uproarious demonstration from the mountain, where, as in the French Revolution, the noisiest spirits congregated. He gave his imaginations full play in comparisons often charming and always quaint. None but Holmes could have compared the microscopical coiled tube of a sweat

gland to a fairy's intestine. You will appreciate the aptness of his likening the mesentery to the shirt ruffles of a preceding generation. He has compared the fibers connecting the two symmetrical halves of the brain to the band uniting the Siamese twins.

As a lecturer he was accurate, punctual, precise, unvarying in patience over detail, and though not an original anatomist in the sense of a discoverer, yet a most exact descriptive lecturer; while the wealth of his illustrations, comparisons and similes was unequalled. Hence his charm. The student received information and was amused at the same time. He was always simple and rudimentary in his instructions. His flights of fancy never shot over the hearers' heads. Iteration and reiteration was his favorite motto in teaching. "These gentlemen," he said on one occasion, pointing out the lower portion of the pelvic bones, "are the tuberosities of the ischia, on which man is designed to sit and survey the works of creation." On another occasion in picking up a female pelvis and pointing to the pubic arch he said, "Gentlemen this is the Triumphal Arch under which every candidate for immortality must pass." But if witty, he could also be serious and pathetic, and he possessed the high power of holding and controlling his rough auditors. In earnest himself, enthusiastic, and of happy temperament he shed the glow of his ardent spirit over his followers and gave to his students some of the most attractive and happy hours of their life.

ESSAYIST

We have not in mind only his contributions to medical science and literature, which, though overshadowed by his work in general letters, were many and important, but we are thinking of that wider province of the physician that lies beyond the laboratory, the drug shop, the hospital and the consulting room, *the education of the public at large*. Dr. Holmes never lost sight of his profession, and he never

allowed the world to lose sight of it. Throughout his writings from "The Fly in the Stethoscope" to the good-natured raillery at a too exclusive specialism in "Over the Tea Cups," he did not hesitate to hit at its weakness and foibles; while apart from the admirable characters in his novels, he has in many noble passages pictured the life and influence of the true, modest and sacrificing doctor, in terms of the highest appreciation. Holmes is best known to English readers through the Breakfast Table Series, the Autocrat, the Professor and the Poet. These were all written when our author was comparatively young. They contain less direct reference to medical ethics than some of his later works, but even in these we note some very pertinent sayings. In the "Later Day Warnings," a short poem in the Autocrat, after dilating on the duties of legislature, haberdashers, preachers and property dealers, there is a fund of philosophy in these two lines:

When lawyers take what they would give
And doctors give what they would take.

He evidently despairs of the attainment of this high ideal, for he ends by saying.

But when you see that blessed day
Then order your ascension robe.

The medical elements are much more noticeable in the "Professor." The following lines are worth remembering by those of us that are apt to look upon ourselves, in our professional capacities, as in the world but not of it.

You can't keep gas in a bladder, and you can't keep knowledge tight in a profession. Hydrogen will leak out and air will leak in, and special knowledge will leak out and general knowledge will leak in, though a profession were covered with twenty thicknesses of sheep-skin diplomas. Till common sense is well mixed with medicine and common manhood with theology, and common honesty with law, we, the people, will crash down upon the lumps of nonsense in all of them, till we have made them like Aaron's calf.

In our relation with patients we might well bear in mind the professor's advice to those about making a choice of a physician:

Be sure you get one with a serene and cheerful countenance. A physician is not, or ought not to be an executioner; and the sentence of death upon his face is as bad as a warrant for the execution signed by the Governor. As a rule no man has the right to tell another by word or look that he is going to die. It may be necessary in an extreme case, but as a rule it is the last extreme of impertinence which one human being can offer to another.

In a discussion as to whether the art of healing makes men hard hearted and indifferent to human suffering, we have a delightful sketch of the ideal doctor in these words:

You may be sure that some men, even among those who have chosen the task of pruning their fellow creatures, grow more and more thoughtful and truly compassionate in the midst of their cruel experience. They become less nervous but more sympathetic. They have a truer sensibility of others pains, the more they study pain and disease in the light of science.

In the Poet, the last of this series, there are some very amusing and highly instructive references to young Doctor Franklin. The following may remind us all of our younger days:

The young doctor has a very small office and a very large sign with a transparency at night big enough for an oyster shop. These young doctors are particularly strong in what they call Diagnosis, an excellent branch of the healing art, full of satisfaction to the curious practitioner who likes to give the latin name to one's complaint; not quite so satisfactory to the patient. Sometimes, in fact, one would rather not know the exact name of his complaint, as, if he does, he is liable to look it up in a medical work, and if he reads, "This terrible disease is attended with vast suffering and is inevitably mortal," or any such statement, it is apt to affect him unpleasantly.

The description of the doctor's office is racy, and I cannot pass on without

relating Holmes description of a patient's interview. I crave your indulgence in this quotation:

With superhuman air of sagacity, with much corrugation of the forehead and fearful concentration of attention Doctor Franklin examined the discolored spot. After dwelling on this most interesting and rare affection and asking if there were any objections to showing the case to the Society of Medical Improvement and Medical Observation, hints are given about Morbus Addisonii. So he gave the patient a prescription, "which," said the poet, "I took care to put where it could do no hurt to anybody, and I paid him his fee, which he took with the air of a man with a great income and said Good Morning. My landlady on seeing the same spot said it was a bump, recommended a piece of brown paper dipped in vinegar; the discoloration soon disappeared." The next interview after Dr. Franklin had had more experience was more satisfactory. The Poet had an ugly cut from a carving knife. It was astonishing to see what a little experience of miscellaneous practice had done for him. He did not ask any more questions about predispositions on the maternal and paternal sides. He did not examine me with the stethoscope and laryngoscope. He only strapped my cut and informed me that it would speedily get well by "first intention."

Dr. Holmes has written three novels all full of medical interest, namely, "Elsie Venner," "The Guardian Angel," and "Moral Antipathy." To begin with "Elsie Venner," this is not the time or place to describe the plot or purpose of the story. I shall therefore dwell on those parts referring to our subject matter. Towards the end of the book we have the following description of Doctor Kettredge:

The old doctor was a model for visiting practitioners. He always came into the sick room with a quite, cheerful look, as if he had a consciousness that he was bringing some relief with him. The way a patient snatches the first look at a doctor's face, to see whether he is reprieved, whether he is unconditionally pardoned or whether he is doomed, has something terrible about it. It is only to be met by an impenetrable mask of serenity, proof

against anything and everything in a patient's aspect. The physician who reflects his patient's condition, like a mirror, may do well enough to examine people for a life insurance office, but does not belong to the sick room. The old doctor came to her (Elsie's bedside), in such a natural quite way, that it seemed that he was only a friend that had dropped in for a moment to say a pleasant word.

In the "Guardian Angel," a delightful story, we will dwell but a moment on one comment of Dr. Holmes on the condition of Myrtle Hazard after she calms down from a series of hysterical attacks. Holmes utters these weighty words:

But all this series of mental disturbance left her in a very impressive state of mind and an excitable condition. This was just the state to invite the spiritual manipulations of one of those theological practitioners who considers that the treatment of all morbid states of mind, short of raving madness, belongs to them and not to the doctors. The same condition was equally favorable for the operations of any professional experimenter, who would use the flame of religious excitement to light the torch of an earthly passion. So many fingers that begin to play on the black keys, stray to the white ones before the tune is played out. Evidently from this we may conclude that the Emmanuel Movement is not of recent origin.

There are many short sayings in this volume which plainly indicate how high Holmes' ethical ideas were. In reference to Myrtle's case I again quote as follows: "Few households have ripened a growth of womanhood without witnessing some of these hysterical manifestations, and its phenomena are largely traded in by scientific pretenders and religious fanatics."

I shall be content with only one more extract from the third volume, in many ways a remarkable book. I refer to "Moral Antipathy." It refers to the ethics of doctors' discussing matters of private interest with their wives. I shall not enlarge as Holmes exactly hits off the danger as follows:

Dr. Butts carried these questions with him. His wife was a sensible, discreet woman,

whom he could trust with many professional secrets. He told her of Paolo's revelation, and talked it over with her in the light of his experience and her own. Mrs. B . . . buried the information in the grave of her memory where it lay for nearly a week. At the end of that time it emerged into a confidential whisper to her favorite sister-in-law, a perfectly safe person. Twenty-four hours later the story was all over the village. Dr. Butts resolves that he would be a little more careful the next time, at any rate, and in spite of every wish to be charitable, he concludes that the worthy lady must have forgotten the rule that "A Doctor's patients must put their tongue out, and a Doctor's wife must keep her tongue in."

From the number of his purely scientific writings on medical subjects, one will always be recalled, "Puerperal Fever as a Private Pestilence." The high estimate in which this work of Holmes is held is demonstrated by the frequent references made to it today by writers on obstetrics. Presuming that all of you have read this medical classic, I am going to quote but one paragraph that has always appealed to me:

It is as a lesson rather than as a reproach that I call up the memory of these irreparable errors and wrongs. No tongue can tell the heart-breaking calamities they have caused; they have closed the eyes just opened upon a new world of life and happiness; they have bowed the strength of manhood into dust; they have cast the helplessness of infancy into the stranger's arms, or bequeathed it with less cruelty, the death of its dying parent. There is no tongue deep enough to record, and no voice loud enough for warning. The woman about to become a mother, or with her new-born infant upon her bosom, should be the object of trembling care and sympathy where ere she bears her tender burden or stretches her aching limbs. The very outcast upon the street has pity upon her sister in degradation when the seal of promised maternity is pressed upon her. The remorseless vengeance of the law brought down upon its victims by a machinery as sure as destiny, is arrested in its fall at a word which reveals her transient claims for mercy. The solemn prayer of the litany singles out her sorrows

from the multiplied trials of life, to plead for her in her hour of peril. God forbid that any member of the profession to which she intrusts her life, doubly precious at that eventful period, should regard it negligently, unadvisedly or selfishly.

Was ever a more beautiful plea made for the expectant mother? Its sentiment is still applicable today.

In the Professor at the Breakfast Table, in comment on this essay, Holmes says:

When by the permission of province I held up to the profession the damnable facts connected with the conveyance of poison from one young mother's chamber to another, for doing which humble office I desire to be thankful that I have lived, though nothing else should come from my life, I had to bear the sneers of those whose position I had assailed, and, as I believe, have at least demolished, so that nothing but the ghosts of the dead women stir among the ruins.

The inquiry is often made as to the exact reason why Dr. Holmes relinquished the practice of medicine. The cause may be found in his farewell address as follows:

Let me begin with my experience as a medical student. I had come from the lessons of Judge Story and Mr. Ashmun in the Law School at Cambridge. I had been busy more or less with the pages of Blackstone and Chitty and other text books of the first year of legal study. More or less I say but I am afraid it was rather less than more. During that year I first tasted the intoxicating pleasure of authorship. A college periodical conducted by friends of mine tempted me into print, and there is no form of lead poisoning which more rapidly and more thoroughly pervades the blood, bones and marrow than that which reaches the young author through mental contact with type metal. "He who has once been a drinker will drink again," says the French proverb, and so the man or woman who has tasted type is sure to return to his old indulgence sooner or later. In that fatal year I had my first attack of lead poisoning and I have never quite gotten rid of it from that day to this. But for that I might have applied myself more diligently to my

legal studies, and carried a green bag in place of a stethoscope and a thermometer up to the present day.

Proud as we are to think of him as a member of our profession, and proud as we are of his achievements in it, we realize that his great work in life had more to do with making people better spiritually than making them well physically. Physician by education, he devoted himself to practice and the acquisition and imparting of scientific knowledge. Poet by nature, he spent his leisure time and declining years in those writings which have so endeared him wherever they have been read. Philosopher, by thoughtful study and love for his fellow men, he made, for many, life's path less rugged by kind and philanthropic words.

The Doctor glided gently and imperceptibly into the period of old age. He came to it in excellent condition both of mind and of body, for he had led a well-regulated life. He had been a hard-working, but never really overworked man, and he had never taken either work or play nervously or tensely. Above all, he had been little preyed upon by anxieties; in the middle path between poverty and riches, with good company, he moved along amid the changing shade of sunshine, by the enchanted hedgerows, enjoying all the possible beauty and peacefulness of the journey through life. In this way he became old by degrees and hardly knew it.

Death drew near with steps so slow, so gently graded that the approach was hardly perceptible. He was out of doors taking his usual walks a few days before the end. He was up and about the house on the last day, and he died, in his chair,

painlessly, as so humane a man well deserved to make his escape out of life, on October 7, 1894.

So passed a way one of the most lovable and notable figures of medicine. A personality pregnant with the perfume of ripe old age, and leaving recollections of a rarely perspicuous and sympathetic insight, a playful and pungent but not caustic humor, and a persuasive benevolence, which was far reaching but discriminating.

Among all his interests two were dominant and transcendent, medicine and literature. By the first he is known to more than a third of a century of students and to the whole medical world, by the second he is known throughout the entire English-speaking world.

In the rush and hurry of our restless life it may be well for us to look back upon the lives of some of the leaders of old, and if by so doing the tension of our mental alertness receives a healthy relaxation, we may consider the time thus spent as not wasted.

"I have only made a nosegay of culled flowers, and have brought you nothing of my own, but the thread that ties them together." Montaigne.

AUTHOR'S NOTE: All claims for originality are waived. This is but a compilation of extracts and paragraphs of many articles that have been read and to whose authors full credit is given for that which I have assembled in an endeavor to transmit a word picture of Dr. Holmes.

F. C. W.

BOOK REVIEWS

A HISTORY OF THE MEDICAL DEPARTMENT OF THE UNITED STATES ARMY. By Colonel P. M. Ashburn. Bost., Houghton Mifflin Co., 1929.

The Librarian of the Library of the Surgeon's General Office should be the logical person to write a well-documented history of

the Medical Department of the United States Army. Colonel Ashburn, the present incumbent of this position, has done the work well. He has not only succeeded in presenting an accurate, authentic work of reference but at the same time has written a volume which makes

interesting reading and he has succeeded in giving what is really an outline of the history of medicine in America. As General Ireland says in the introduction, the story of this department is "a story of honest effort, of continual striving, of unselfish service, of steady improvement, of very honorable and very great achievement, a story we should like for the world to know." General Ireland is too modest in his statements. The story is one that the world of medical men at least *should* know. The story is one of organization, of scientific investigation, of heroism and self-sacrifice. Called upon in the Army posts to handle the usual functions of the family physician, the medical department of the United States Army is at the same time required to handle the most intricate problem of tropical medicine. The laboratory and operating room are of equal importance to this department.

Colonel Ashburn tells his story chronologically and divides it into six parts. Part I covers the Revolution, the War of 1812, the Indian Wars, the Mexican Wars and the Civil War. Parts II and III take from 1873 through the Spanish-American War. Part IV covers the interim between the Spanish-American War and the World War. The latter is covered in Part V, Part VI bringing the work from the World War to date. This volume offers to the surgeon of today not only a literary treat but many surprises as to the activities and interest of "our medical department." If this book is purchased by only a small number of those who *should* read it, a new edition will soon be called for.

BIOGRAPHISCHES LEXIKON der hervorragenden Ärzte aller Zeiten und Völker. Zweite Aufl. herausg. und bearb. von Dr. med. et phil. Franz Hübner, Berlin. Erster Bd. Aaskow—Chavasse. Mit 64 Bildnissen, 936 Zeite. Berlin, Urban & Schwarzenberg, 1929.

"Hirsch's Biographisches Lexikon," published in 1883, has long been the chief source book for biographic material for medical historians. Out of print for some time, it has of recent years been high priced and unavailable to most historians. The new edition is, therefore, particularly welcome at the present time when interest in medical history is being stimulated in all directions.

Carefully edited, printed in a type easy to read, typographically well arranged and with a splendid collection of portraits, with biographic material as to dates of birth, death and

publications readily accessible, the new edition will form a necessary part of the armamentarium of everyone interested in medical history. This today should include practically everyone practising medicine. The new edition is to be complete in 6 volumes, of which only the first is published. We look forward with keen anticipation to the publication of the other volumes and if they are the equal of the one before us, the set will leave little to be desired.

Among the Americans in the present volume are William B. Beaumont, Gurdon B. Buck, J. M. A. Allen, Timothy F. Allen, Henry F. Campbell, John B. and Samuel Bard, etc., from which it will be seen that the "Lexikon" is rather complete.

It is unfortunate to find Sir Thomas Clifford A. Allbutt's name spelled "Alibutt," but a few misprints are unavoidable in a work of this kind and undoubtedly will be taken care of in the reprints.

KYKLOS. Jahrbuch des Instituts für Geschichte der Medizin an der Universität Leipzig. Band I. 172 pp. 1 illus., 1928. Band II. 299 pp. 9 illus., Leipzig, Georg Thieme, 1929.

The first volume, published in January, 1928 and the second of January, 1929, give indications of year books that will be expectantly looked forward to by all interested in medical history. That Volume II should be dedicated to our own Dr. William H. Welch and have his portrait as a frontispiece is a particularly apt tribute at this time when the Welch Institute for Medical History has just been opened in Baltimore. The splendid dedicatory foreword to Dr. Welch is but another example of the internationalism of science. A list of the contents of each volume is appended. The authors and subjects need no comments. No student of the history of medicine will want to be without these volumes and every physician would profit by their perusal. The contents of the two volumes follow:

VOLUME I:

Vorwort.

1. Abhandlungen aus dem Institute. Der systematische Zusammenhang im Corpus Hippocraticum. Von Owsei Temkin. Zur Grundstruktur der paracelsischen Naturwissenschaft. Von J. D. Achelis. Time-implied Function: an historical Aperçu. By Stephen d'Irsay. Kultur und Krankheit. Von Henry E. Sigerist. Die Alliumarten im Gebrauch der abendländischen Medizin. Von Kurt Heyser Sapientia

artis medicinae. Ein frühmittelalterliches Kompendium der Medizin. Von M. Wlaschky. Ein frühmittelalterlicher Botanicus. Von Erhardt Landgraf.

II. Aus Forschung und Lehre der Medizingeschichte. Die Geschichte der Medizin im akademischen Unterricht. Ergebnisse einer Rundfrage des Instituts. Von Henry E. Sigerist. An historical Dictionary of Medicine. By Stephen d'Irsay.

III. Bericht über die Tätigkeit des Instituts im Jahre 1926/27. Register.

VOLUME II:

Vorwort.

1. Abhandlungen aus dem Institut.

Die Sonderstellung des Kranken. Von Henry E. Sigerist. Studien zum "Sinn"-Begriff in der Medizin. Von Owsei Temkin. 1. Kritisch-logische Voruntersuchung. 2. Krankengeschichte und Sinnsphäre der Medizin. 3. Moliere und der Sinn der Medizin im 17. Jahrhundert. 4. Epidermiologie und Geschichte der Medizin. Virchow. Von Ernst Hirschfeld. A physiological synthesis. By Stephen d'Irsay. Fragmente zur Arzneygeschichte. Von Hermann Scheer. 1. Warum treiben wir heute Geschichte der Heilmittel? 2. Einleitung zur Geschichte einer Heilpflanze. 3. Mensch und Pflanze. Studien zur Geschichte der Heilpflanzen. 1. Lilium convallium. Von Ernst Hirschfeld. 2. Scilla. Von Ernst Hirschfeld. 3. Zur Geschichte der medizinischen Verwendung des Safran (*Crocus sativus*). Von Maria Tscholakowa. Die Personallehre in der Naturphilosophie von Albertus Magnus. Von Claudius Franz Mayer. Diätetische Wundbehandlung im Mittelalter. Von August Wilhelm Bock. Eine Beschwörung der Gebärmutter aus dem frühen Mittelalter. Von Werner Bernfeld.

II. Aus Forschung und Lehre der Medizingeschichte. Bibliographie der medizingeschichtlichen Arbeiten Karl Sudhoffs aus den Jahren 1923-1928. Nach Materien geordnet von Grete Herbrand.

III. Bericht über die Tätigkeit des Instituts im Jahre 1927/28 Register.

THE VOLUME OF THE BLOOD AND PLASMA IN HEALTH AND DISEASE. By Leonard G. Rountree, M.D., and George E. Brown, M.D., with the Technical Assistance of Grace M. Roth. Phila., W. B. Saunders Co., 1929.

This modest volume is a Mayo Clinic Monograph and its value is guaranteed by the authors, alone, even though the subject is one of great present-day importance. Every

general practitioner who pretends to thorough scientific work and every internist may well spend two or three hours with this book. W. J. Mayo says in the Foreword: "Studies of blood volume give a new outlook on many problems which long were considered settled . . . The pure science of to-day is the applied science of tomorrow."

This book presents the evidence which has accumulated during the last few years relative to observations made with the dye method. The authors have shown the value of the study of the blood volume and plasma volume in clinical medicine.

We earnestly recommend this book.

THE LIFE OF HERMANN M. BIGGS, M.D., D.S.C., LL.D. Physician and Statesman of the Public Health. By C.-E. A. Winslow, DR. P.H. Phila., Lea & Febiger, 1929.

We are here offered the life history in simple language of one of the outstanding figures in modern American medicine. Some of the interesting sidelights taken up include medical science, hospital organizations, public health work and politics from 1859 to 1923. As Dr. Welch says in his preface "Biggs had a genius for leadership and has been justly called a sanitary statesman." The book should prove a source of inspiration to every young physician and medical student. It is truly an idyll of American achievement.

DIE WIEDERBELEBUNG. By Oskar Bruns and Karl Thiel. Berl. Urban & Schwarzenberg, 1930.

This little book on resuscitation should be found interesting and valuable to physicians and surgeons connected with industrial plants. The claim is made by the author that with proper knowledge of resuscitation many an apparently hopeless case, suffering only from electrical shock, may be saved. The subject is well covered and should be in the medical library of every industrial plant today.

ESSENTIALS OF MEDICAL ELECTRICITY. By Elkin P. Cumberbatch, M.A., B.M. (Oxon.), D.M.R.E. (Camb.), M.R.C.P. Ed. 6, rev. & enl. 11 pl., 116 illus., 459 pp. St. Louis, C. V. Mosby Co., 1929.

The sixth edition of this book has been carefully brought up to date. It gives, as its title indicates, the "essentials of medical electricity" as understood at the present time.

PSYCHIATRIE DU MÉDECIN PRATICIEN. By M. Dide and P. Guiraud. Ed. 2. Paris, Masson et Cie, 1929.

Here is a modern, well-written and well-illustrated textbook on psychiatry written for

the general practitioner and of undoubted value to those reading French.

THE PATHOLOGY OF THE EYE. By Jonas S. Friedenwald, M.D. N. Y., Macmillan Co., 1929.

"This book," says the author, "is the outcome of a course of lectures, . . . for the instruction of medical students and surgical house officers in the department of ophthalmology of the Johns Hopkins Medical School and Hospital." As far as may be done in a volume of 350 pages, the author has covered his subject well and, while not intended for specialists, as a comprehensive survey of the subject the book presents a splendid outline of the pathology of the eye for the non-specialist.

THE MEDICAL MUSEUM. Based on a New System of Visual Teaching. By S. H. Daukes, O.B.E., M.D., D.P.H. Lond., Wellcome Foundation, Ltd.

This, the latest publication of the Wellcome Foundation, is not merely a theoretical discourse on medical museums but a report of definite progress. Everyone interested in museums from any angle will profit by a study of this book.

AIDS TO ORTHOPAEDIC SURGERY. By Eric A. Crook M.CH. (Oxon.), F.R.C.S. (Eng.). N. Y., William Wood & Co., 1929.

This volume on orthopedic surgery aims, according to the author, to cover only "that part of the subject of which knowledge is required of the student of general surgery." This purpose is accomplished by the book and not only the student but the general surgeon will find the scanning of this book an excellent method of refreshing his knowledge of orthopedic surgery.

RESEARCH AND MEDICAL PROGRESS AND OTHER ADDRESSES. By J. Shelton Horsley, M.D., Richmond. 6 illus., 208 p. St. Louis, C. V. Mosby Co., 1929.

This volume of 15 essays by Dr. Horsley, of Richmond, Va., covers a great deal of ground as indicated by the following titles of the chapters: Research and Medical Progress; Physiology and Modern Surgery; The Influence of Physiologic Research on Modern Surgery; The Ideals of the Surgeon; The Career of a Surgeon; Shall Surgeons Tell the Truth?; Stomach Trouble; The Mimicry of the Symptoms of Peptic Ulcer; Peptic Ulcer and Cancer of the Stomach; Some Considerations Concerning the Treatment of Cancer; Modern Methods of Preoperative and Postoperative Treatment; The Medical Profession

of Virginia; The Medical Profession of Virginia and State Medicine; Politics and Medicine; The Virginia Academy of Science—Our Fifth Estate. Dr. Horsley also has always something worth saying on each subject and says it well. The volume will repay the short time taken to read it.

ETUDES SUR LES MALADIES FAMILIALES NERVEUSES ET DYSTROPHIQUES. By O. Crouzon. 90 illus., 395 p. Paris, Masson et Cie, 1929.

This book with a preface by Prof. Pierre-Marie covers the subject in a complete and up-to-date manner and presents completely and concisely the ideas of the French school today. Every neurologist and neurosurgeon, who reads French, will want to add this book to his library.

SURGERY OF THE LUNG AND PLEURA. By H. Morriston Davies, M.A., M.D., F.R.C.S. Oxford Press, 1930.

This is a monograph in a series entitled Regional Surgery.

To any surgeon who wishes to keep abreast of the times this book is presented; to the surgeon who deals with affections of the lung and pleura we recommend this well-written and thorough addition to the literature. We feel that the casual surgeon should not attempt many operations made necessary by diseases of the lung and pleura; it is a field for the mature and especially well-trained man, but to the student of surgery and the growing assistant this volume will prove an invaluable aid.

In the last two decades surgery of the lungs and pleura is a bright light in the field of surgical advance and the author of this work handles his subject sanely and thoroughly; the reader soon senses he is reading a finished authority on the subject.

THE TREATMENT OF VARICOSE VEINS OF THE LOWER EXTREMITIES BY INJECTION. By T. Henry Treves-Barber, M.D., B.Sc. N. Y., William Wood and Co., 1929.

This small book of 120 pages gives in every detail essential to the practitioner the technic of the injection treatment of varicose veins of the lower extremities. In a readable and concise manner the author covers the essentials of the modern ambulatory treatment of this common condition. In these days when many men attempt this treatment with an inadequate knowledge of the contraindications, possible complications during treatment and with no

knowledge of the pathology involved it would not be amiss to urge that this worthwhile book be in the hands of many of the profession.

HEMORRHOIDS. The Injection Treatment and Pruritus Ani. By Lawrence Goldbacher, M.D. Phila., F. A. Davis Co., 1930.

In the preface the author writes: "The purpose of this book is to present to the medical profession certain practical and readable information regarding hemorrhoids and pruritus ani. The aim has been to make it as brief and simple as possible." The author has succeeded. To any physician interested in these subjects we would be neglecting our duty if we did not write that this small book is a necessary part of the literature and just what a majority of busy doctors of medicine have been looking for.

TONSIL SURGERY. By Robert H. Fowler, M.D. Phila., F. A. Davis Co., 1930.

To the true laryngologist this book will prove interesting and the reader will be pleased with the excellence of the publishers' part of bringing it out. The type is large and the illustrations (half-tone and colored) are well reproduced.

To the man who thinks tonsil operations are a part of the general practice of medicine we would like to be able to command that this book must be read ten times and then studied for two years. After this course of reading and study we feel he would be an aid to the public and really know how to do tonsil surgery. That the author has accomplished his aim is sufficient recommendation to any who feel they want a book on this subject.

TREATMENT IN GENERAL PRACTICE. By Harry Beckman, M.D. Phila., W. B. Saunders Co., 1930.

This is a necessary book to most physicians. The average student graduates from a medical school well grounded in pathology, physical diagnosis, etc., and except for a few inadequate lectures, it is left to the future for him to discover how to treat his patients. Very often this is accomplished by the literature of drug houses and the beguiling tongues of detail men. And so Dr. Beckman's book is

thrice welcome. We will not go into details but merely leave you with this instruction: If you practice medicine and want a handy book to which you can turn to guide and find advice when in a quandary as to treatment this work is the one we hint that you will not go amiss in buying.

THE TREATMENT OF COMMON DISORDERS OF DIGESTION. By John L. Kantor, PH.D., M.D. Ed. 2. St. Louis, C. V. Mosby Co., 1929.

The second edition of this book follows closely the lines of the first edition. Three new chapters have been added on "Common Anomalies of the Colon," "Irritable Colon (Colitis)," and "Organic Diarrheas." There is new material on the vitamins, neutral antacids, cardiospasm, modified Sippy diet, surgical treatment of ulcer, after-treatment of ulcer, etc. For a practical survey of the treatment of the common disorders of digestion the book may be highly recommended.

MAMMALIAN PHYSIOLOGY. A Course of Practical Exercises. By E. G. T. Liddell, D.M., and Sir Charles Sherrington, O.M., M.D., D.Sc., F.R.S. Ed. 2, Oxford Univ. Press, 1929.

This is a laboratory book which should prove invaluable to the student of physiology. Having stood the test of two editions, and written by that master physiologist, Sir Charles Sherrington, it may be considered today the last word on the subject.

ACUTE INFECTIOUS DISEASES. By J. D. Rolleston, M.D. Ed. 2. Lond., Wm. Heinemann, 1929.

The first edition of this book was published four years ago and the second edition has brought those chapters in which advances have been made up to date. The principal changes have been made in the chapters on diphtheria, typhoid fever, scarlet fever, measles, smallpox and vaccinia. The fact that only one paragraph is devoted to undulant fever and one to tularemia will probably be disappointing to American physicians. It is to be hoped that in the next edition these subjects will be more elaborately treated. The systematic method of handling the subject, the simple language, and the evident authority with which the author speaks make this book an interesting work of reference.

SUPPLEMENT TO

The American Journal of Surgery

A CLINICAL STUDY OF THE
ABDOMINAL CAVITY AND PERITONEUM

EDWARD M. LIVINGSTON, M.D.

A CLINICAL STUDY OF THE ABDOMINAL CAVITY AND PERITONEUM

SECTION I. THE CAVITY*

C. THE ABDOMINAL WALLS

2. The Bony Walls (Continued)

THE shape of the abdominal cavity is basically that of a truncated ovoid, but the symmetry of this figure is destroyed by the ingrowth, on the posterior wall, of the vertebral column. The cavity is narrower in the anteroposterior than in the transverse diameter and the narrowest point is situated over the fourth and fifth lumbar vertebrae, or just above the sacral promontory (Fig. 35). During physical examinations this prominent vertebral mass may sometimes be felt, when palpating the anterior abdominal wall. By bearing in mind how closely the anterior and posterior walls may approach one another in the lower lumbar region, the clinical blunder of mistaking the vertebral mass for some abnormality within the peritoneal cavity may be avoided. In confusing cases palpation is best conducted beneath a fluoroscopic screen.

The Lumbar Curvature of the Spine

The abdominal aorta courses along the anterior surface of the vertebral column, running slightly to the left of the midline, and bifurcating at the level of the fourth lumbar vertebra to form the right and left common iliac arteries. It may be mistaken during palpation for a pulsating tumor (aneurysm or solid tumor overlying the aorta). There are instances in which this great vessel may actually be rolled from side to side beneath the palpating fingers as an elongated cordlike mass (Fig. 35, note 2). As a result the diagnostician

Palpating the Abdominal Aorta

* Preceding installments have appeared as follows: January issue, p. 193; February issue, p. 460.

FIG. 35. Cross section of abdomen showing the narrow anteroposterior diameter in the lumbar region.

Note. 1. The vertebral column is often palpable through the anterior abdominal wall and may be mistaken for an abnormal mass.

2. The abdominal aorta frequently may be palpated immediately below the umbilicus.

3. A blow upon the anterior abdominal wall may cause injury or rupture of an intestinal loop by crushing the intestine against the vertebral column.

may be taxed to the limit in his effort safely to identify that which is normal and to exclude that which is abnormal. When the abdominal aorta is plainly felt during an examination, the information which it may impart should not be ignored. It is possible, through palpating this vessel, to estimate the cardiac rate, vigor and regularity. At times this information may be thus obtained with even greater facility than through feeling the radial artery, partially obscured, as it is, between the styloid process of the radius and adjacent tendons. The abdominal aorta is the largest palpable vessel in the body. When seeking other information by abdominal examination the surgeon should add to his observations such data as may be gained through palpating this artery, even though the additional information be recorded in an almost subconscious manner. By such a routine the attention need not be directly diverted to the vascular system but many gross circulatory abnormalities may automatically be detected.

Within the *epigastrium* pulsations from the abdominal aorta are not normally felt. Thorkild Røvsing pointed out⁴¹ that aortic epigastric pulsations occur here only with malpositions of the stomach; he wrote (clinical lectures):

Epigastric Aortic
Pulsations

One perceives a distinct pulsation in the epigastric region, as I place my hand on the epigastrium, and I feel the aorta pulsating quite close to my finger; you can see, in fact, how my fingers rise and fall simultaneously with the pulse wave. You will never find this with individuals whose stomachs occupy their normal positions. It is merely due to the fact that the stomach, which usually covers the vertebral column like an air- or water-cushion, has glided down from its position into the lower abdomen. It is, therefore, a pathognomonic sign of gastropptosis.

3. *The Soft Parts as a Whole.* Much space is allotted in most surgical reviews of the abdominal walls to a study of incisions and of the anatomy of hernias. The present chapter, however, deals but little with either topic for both are subjects in which the operating surgeon is well versed and both are excellently presented for review in many readily obtainable texts. It has been said (Ochsner) that the "innumerable

The Anatomy of
Hernias; Abdomi-
nal Incisions

abdominal incisions which have been described by, and bear the names of, innumerable surgeons" represent that type of non-essential information which exists in many surgical fields and serves to add needless confusion; it represents "a pedantry which often clutters and obstructs the profession." The present aim is intentionally to omit much that is elementary and to avoid confusing non-essentials. The primary object is to suggest new angles from which to consider surgical topics and to attain such an objective it is inevitable that routine values often be disregarded and a logical arrangement of material sacrificed. "To be truly a postgraduate study the topics must be elective." The anatomy of inguinal hernias, then, will be entirely omitted from discussion and details as to methods for incising the peritoneal cavity will be referred to only as the subject arises in other connections.

Injuries to the Abdominal Wall

The most important diagnostic problem in regard to wounds of the abdominal wall is to determine whether intra-abdominal structures have been simultaneously injured. It is well known that the same violence causing a simple or closed wound of the belly wall may also produce an open wound (rupture) in some viscus. Morgagni⁴² described the mechanism by which the intestine might be crushed against the vertebral column while the anterior wall itself showed little evidence of injury (See Fig. 35, note 3). The literature on this subject has been reviewed by Royster⁴³ and others.⁴⁴ Correct diagnosis is of vital importance for when the pain, shock, tenderness and rigidity are due solely to a solution of continuity within the wall itself, laparotomy is needless; but in the presence of intraperitoneal hemorrhage or leakage of contents from some viscus, an immediate operation is imperative. When it seems certain that the anterior wall alone has been damaged the treatment consists essentially of securing muscular relaxation through posture (flexed thighs, elevated head) and of making appropriate local applications (wet dressings, straps); open wounds are closed in layers, with or without drainage; probing an abdominal

wound is inadvisable. When, upon the other hand, an intra-abdominal injury is known to have occurred, or is strongly suspected, and preparations are being made for operation, the patient should promptly be placed in a semi-sitting posture (Fowler or exaggerated Fowler position) in order to encourage the gravitation of fluids to the pelvis, and adequate doses of morphine should be administered to diminish shock and to quiet the intestinal musculature.

Abdominal Perforations

Complete perforation of the abdominal wall constitutes an indication for early exploration to allow prompt repair of damage to any viscus.⁴⁵ It has been stated that "the safest treatment for a stab wound that penetrates, or which is suspected of penetrating, is early, careful exploration."⁴⁶ About 90 per cent of all gunshot or stab wounds perforate some organ, or organs, over half being those of the intestinal tract. Isolated cases have been reported in which spontaneous closure of small perforations of bowel have undoubtedly occurred⁴⁷ and this is explained by the plugging of the aperture by redundant mucous membrane or by omentum and by a reduction of the size of the perforation through a reflex contraction of the intestinal muscles adjacent to the wound.⁴⁸ Upon the basis of such reports conservatism might seem permissible when the perforating foreign body is known to have been of small calibre and particularly when the wound is in the upper abdomen, the patient not in shock, and proper conditions for operation not at hand. Yet such delay based upon theoretical grounds and upon isolated or chance reports is not a true conservatism, for early favorable symptoms are frequently followed by sudden fatal collapse and the two chief causes of death following perforation are hemorrhage and peritonitis, neither of which brooks delay. Authorities,⁴³⁻⁴⁵ almost without exception, agree that the outcome of untreated perforations of the intestinal tract is "practically a 100 per cent mortality." Delore went so far as to state that in 1500 cases no patient with a penetrating abdominal wound had recovered under conservative treatment.⁴⁹ Even with operative

interference the mortality following gunshot wounds of the abdomen has been found to be 50 per cent both for civil⁵⁰ and war practice.⁵¹ It is definitely established, however, that the end-results bear a direct relation to the promptness of operation, just as is true of the operative results from acute peptic perforations where every hour of delay adds to the danger; and in 700 cases studied with reference to the time of operation the mortality varied from 18 per cent in those operated upon within four hours to 87 per cent where operation was delayed beyond twelve hours after injury.⁵²

Evidences of Intra-
Peritoneal Injury

Intra-abdominal damage is indicated by characteristic pain, vomiting, persistent shock, and evidences of internal hemorrhage or visceral leakage. (Fig. 36.) Included in this evidence may be dyspnea, rapid pulse, pallor, shoulder pain, hiccough, absence of liver dulness, shifting dulness in the flanks, leucocytosis, subnormal temperature, absent reflexes. The pain is deep-seated and widespread and is usually first referred to the umbilical region. Associated with shock is cold perspiration, typical pallor, respirations which are superficial and rapid, and a pinched and worried expression which is not readily mistakable. The shock is due to overstimulation and paralysis of the vital reflex centers, vasomotor and respiratory. The vomiting is a reflex through the vagus and it occurs immediately after the injury, but this may be followed by a persistent or recurrent vomiting, often of a mechanical type. Hemorrhage is indicated by a soft and rising pulse, by increasing pallor, "air hunger," and thirst; the leucocyte curve following subserous hemorrhage is characteristic,⁵³ the count rising rapidly within the first few hours to a 200 or 300 per cent increase above normal, reaching a peak before the sixth hour, and returning slowly to normal by the fourth day; thus interval blood counts studied with reference to the time after injury are of great value. The free fluid gives rise, at times, to shoulder pain, hiccough, and shifting dulness; free gas, even in small quantities, may cause an early obliteration of liver dulness (see section on Intra-abdominal Pressure).

FIG. 36. Graphic study of some signs and symptoms caused by intestinal perforation.

[97]

The local examination is of questionable value, since tenderness and rigidity accompany injuries to the abdominal wall as well as those to the viscera. These individual signs and symptoms will be minutely studied in the sections headed Visceral Neurology, The Intestinal Tract, The Solid Organs, and The Peritoneal Membrane. In addition to the general evidences of intraperitoneal involvement are the signs and symptoms of injuries to specific structures. For example, rupture of the bladder may be indicated by such findings as bleeding from the urethra, local extravasations of urine, and an empty bladder upon catheterization. Perforation of the diaphragm, with subsequent diaphragmatic hernia formation, should be considered after any perforating wound in the upper abdomen. Even though the indications of intra-abdominal injuries are numerous and well defined, the following conclusion has repeatedly been restated by many authorities:

There is no sign, or combination of signs, sufficiently constant to indicate the nature of the injury in every case, or to serve as a basis for diagnosis. Exploration is the only definite means for making a diagnosis in season for effective treatment. To wait for definite intraperitoneal signs is often to wait too long, and we should not be deceived into a false sense of security by an improvement in the early symptoms.⁵⁴

Muscle Strain in
the Anterior Ab-
dominal Wall

Simple strains of the muscles of the anterior abdominal wall may give rise to signs and symptoms which are readily mistaken for those from more serious affections such as early appendicitis, inguinal hernia, obstructions to the ureter. Such muscle strains should be chiefly thought of with two classes of patients: the young school girl who strains her oblique muscles from vigorous activities to which she has been unaccustomed and the middle-aged man when first resuming strenuous sports after having gained considerable weight.⁵⁵ It is important, then, in taking the history in atypical abdominal cases to include an inquiry into any unusual physical exertion during the preceding fortnight.

Desmoid Tumors

It is often difficult to determine whether a given palpable mass is located within the abdominal cavity or within the

abdominal wall. Tumors within the wall itself may exist anterior to the muscles, within the substance of the muscles or beneath the muscles; again, they may be herniated through the muscle layers. Those which are herniated may be detected by their impulse upon coughing; those beneath the muscles are obscured when voluntary rigidity occurs; those within the muscle become fixed and hard as the muscle is contracted whereas they were previously movable; and those situated above the muscles are rendered more prominent as the contractile tissue beneath is made tense. Neoplasms intimately connected with the abdominal muscles are rare, except for the variety known as desmoid tumors or the recurrent fibromata of Paget.⁵⁶ Among salient points concerning desmoids are the following; By definition the term means "resembling in appearance a tendon or ligament; ligamentous, tendinous; of firm texture, noting a fibroid or scirrhus tumor" (Gr. *desmos*, a band (tendon) + *eidos*, appearance or form). Desmoids arise, for the most part, in the posterior sheath of the rectus. Rarely are they found in the sheath of the oblique muscles. In three-fifths of all cases they arise in women during pregnancy and are here of rapid growth. This origin is presumably accounted for by minute tears in the muscle and fascia caused by stretching of the belly wall. With women the age incidence is from twenty-five to thirty-five (most active period of reproduction); with men, when desmoids arise, they occur between the thirty-fifth to the fiftieth years. The tumors may be multiple, but as a rule are single. There is a distinct predilection for the lower half of the abdomen and desmoids are more frequent on the right side than on the left. These masses may be slow in growth; when developing rapidly during pregnancy they may diminish in size after parturition. Their typical shape is spherical but this may be modified by the muscle fibers through which they are forced, hence the tumors may become ovoid, or flattened, or have a collar-button shape. When passing beyond their usual size of that of a walnut or egg they take on the characteristics

of a fibromyxoma or fibrosarcoma and may become huge. The typical tumors are hard and solid, with a firm capsule more or less adherent to surrounding tissue. On section the neoplasm has a definite sheen and a tendon-like appearance; it creaks under the knife; its center may show evidences of hemorrhage or calcification. Microscopically, in addition to the typical seeds there may be clusters of rapidly proliferating spindle or round cells and only the postoperative clinical history serves to definitely rule out the diagnosis of sarcoma and establish that of desmoid tumor.⁵⁷

The Line of Congenital Anomalies and Embryonic Defects

The exact midline of the body has been referred to as "the line of embryonic defects." It represents the final site of closure between the two lateral walls of the trunk. Such defects as the following occur along the midline: umbilical hernia, patent urachus, persistent Meckel's diverticulum, epigastric hernia, ectopia vesicae, spina bifida, meningocele, dermoid tumor, imperforate anus. The trained clinician will consider the possibility of an embryonic origin in any tumor, cyst, or fistula which occupies the exact midline of the body. When aware of the congenital nature of the lesion the surgeon is prepared to take the special care or to adopt the special operative procedures usually required with this class of conditions.⁵⁸

Epigastric Hernias

The linea alba between the navel and the ensiform cartilage is at times the seat of small masses varying in size from that of a walnut to that of an egg, known as epigastric hernias (Fig. 37A). The usual site of these little tumors is within 3 in. of the umbilicus. They are of congenital origin and may be of four varieties:⁵⁹ (1) Small masses of subperitoneal fat without a sac; (2) such fat tabs with the addition of processes of peritoneum, but without hernial contents; (3) a peritoneal sac containing omentum; (4) a peritoneal sac containing intestine (Fig. 37B). While symptoms may be absent they are often severe, including nausea, vomiting, hematemesis and epigastric pain. The diagnosis of peptic ulcer is often made in the presence of such symptoms, the congenital mass being entirely

overlooked. The confusing symptoms are due to the "dragging" on upper abdominal structures. An operative cure is not difficult to obtain through the use of the Mayo technic

FIG. 37A. The chemical picture of epigastric hernia. (From Quervain.)

FIG. 37B. The anatomical varieties of epigastric hernia. (epigastric hernia and subserous lipoma). (From Quervain.)

(d) Simple epigastric hernia, without lipoma.

for dealing with small umbilical weaknesses. The removal of such tumors, though small, should only be attempted

under the most rigid aseptic conditions and under circumstances which make possible a much more extensive procedure than would at first seem required, including intra-abdominal manipulations.

The Navel

4. *The Umbilicus.* The umbilicus is of particular interest to the surgeon on account of its location, its permanent venous connections with the portal circulation and its historical relations to the bladder, intestinal tract, liver, vascular system, and peritoneal cavity.

Spontaneous Cure of Umbilical Hernia in Infancy

The word umbilicus means (L.) a small pebble or button (the belly-button) and may be used in a non-medical sense for any object which resembles a little pebble, or again, for any small pit or fovea into which such a tiny pebble might fit (an umbilication). The central depression or umbilication of the abdominal wall is caused by an internal traction exerted by obliterated embryonic vessels (the ligaments of the umbilicus). This traction accounts for the spontaneous cure shortly after birth of most congenital umbilical weaknesses. The central location of the umbilicus is implied in the synonym, navel, for, as the hub of a wheel is its nave, or the nave is the name applied to the central portion of a church, so the human navel is a close approximation to the central point on the anterior abdominal wall. The exact location varies considerably, being relatively low in early childhood, and still lower with great corpulency, but is normally situated just above the level of the iliac crests, or opposite the disc between the third and fourth lumbar vertebrae. A third synonym, derived from the Greek, *omphalos* (retained as omphalocele, umbilical hernia; omphalic duct; omphalitis, etc.) likewise means a central object, and was the name of a stone located in the temple of Apollo at Delphi, supposedly marking the exact center of the earth.

The Omphalos

Umbilicus and the Portal Circulation

For purposes of description the functioning structures at the umbilicus might be termed its "live" parts and those which are purely vestigial, its "dead" parts. Perhaps the most important of the former are the veins which connect the umbilical region and the portal circulation. These travel

from the navel along the round ligament of the liver to empty into the left branch of the portal vein as it crosses the umbilical fossa. Umbilical infections may thus drain into the portal

FIG. 38. The caput Medusae.

circulation to cause a secondary pylephlebitis (*pyle*, a gate, phlebitis, inflammation of portal venous system). Again, in cases of portal obstruction from diseases of the liver, back pressure often develops within these veins, causing congestion about the umbilicus. If the obstruction is complete, blood from the portal veins distal to the obstruction may actually flow out through the umbilical veins to reach the systemic circula-

Caput Medusae

tion through an anastomosis about the navel with the superficial epigastric veins. This gives rise to the phenomenon known clinically as the "caput Medusae" (Fig. 38), so called because of the presence of bluish, radially distributed, snake-like periumbilical veins (Medusa, a mythological character whose hair was transformed into serpents).*

"Live Structures of the Navel"

Concerning the other "live" structures of the navel: the nerves are terminal filaments of the anterior branches of the tenth thoracic trunks, interosculating with filaments from the ninth immediately above and the eleventh immediately below; the lymph glands are two, sometimes three in number, lying in the perperitoneal fat, one below and one or two just above the navel, the lower gland draining through lymph vessels to the external iliac glands, and the upper set draining the upper portion of the umbilicus to empty, by efferent vessels, into the inferior anterior mediastinal glands; the arterial supply is chiefly from the superior and inferior epigastric arteries, the former coming from the subclavian artery by way of the internal mammary artery and the latter from the external iliac artery, while both anastomose freely with adjacent branches of the intercostal arteries. The veins, in addition to the ones accompanying the round ligament, follow the arteries and thus ultimately drain both to the inferior and superior venae cavae. Many significant facts regarding these anatomical details are subsequently considered. This brief review merely serves to further the ease with which these essential minute points may be stored in the memory.

Vestigeal Structures at the Umbilicus

The umbilicus is connected to the bladder by means of a median umbilical ligament (Fig. 39). This is a remnant of the urachus (Greek word for urine) which is that portion of the allantois lying within the body of the fetus. (The allantois, from Gr. sausage + appearance, is a fetal membrane which enters, internally, into the formation of the bladder, and externally into the formation of the umbilical cord and

* Further consideration is given to the portal and "caval" collateral veins in the sections dealing with ascites and intraabdominal pressures.

placenta). The point of attachment to the bladder of this median ligament is at the bladder vertex. Rarely the urachus fails to close completely, forming a second opening between

Patent Urachus

FIG. 39A. Ligaments of the umbilicus.

The median umbilical ligament represents a remnant of the urachus and connects with the bladder vertex. The lateral umbilical ligaments represent the obliterated umbilical arteries and pass to the hypogastric arteries. Note the peritoneal folds or plicae over the ligaments and the peritoneal fossae between the ligaments. (From Hertzler's *The Peritoneum*, Mosby.)

the bladder and the body surface, and causing a discharge of urine or cellular debris from the navel.

To the side of the median ligament run the two lateral umbilical ligaments. These lie beneath the peritoneum,

Significance of the
Navel Connections
with Vascular
Trunks

(plicae lateralis). They pass over the pelvic brim to join the hypogastric arteries (Fig. 39B) (dextra and sinistra). These stout fibrous cords represent the obliterated umbilical arteries.

FIG. 39B. Umbilical vessels of the fetus. (From Gegenbaur.)

Their proximal portion, however, is not entirely obliterated, and enough remains patent to give origin to the superior vesical arteries. The chief significance to the surgeon of these lateral ligaments is that they explain the infraumbilical plicae in the peritoneum and that they serve as guides or points of direction. They may prove especially valuable to the surgeon when he is operating in the pelvis where extensive inflammation or neoplastic infiltration has rendered the field obscure. The round ligament of the liver is a fibrous cord derived from

the obliterated left umbilical vein. It travels from the navel to the left branch of the portal vein within the folds of the falciform ligament (described with the liver). Thus in carrying a midline incision past the umbilicus it is necessary to cut to the left of this structure in order to avoid cutting the round ligament. Upon the other hand, the surgeon may intentionally cut the round ligament in order to facilitate rotation of the liver around its transverse axis when unusual difficulty has been experienced in exposing the cystic and common bile ducts. In such instances the ligament is to be repaired before the abdomen is closed.

Rotation of Liver

From this summary it is seen that in the fetus three vessels pass through the umbilicus, the vein travelling directly upward and the two arteries travelling obliquely downward within the abdominal cavity (Fig. 39B). One remaining fibrous cord from an obliterated vessel is inconstantly present at the umbilicus, namely a band passing from the superior mesenteric artery, over the intestinal wall to the navel and representing an old means of nourishing; the primitive yolk sac.⁶⁰ (The origin and significance of this cord may be read in the original words of Meckel in the section dealing with eponyms, p. 128.) Such a free band, when present, passing from gut wall to umbilicus, may be the cause of an internal hernia, or band obstruction of the bowel.

The most common connection between umbilicus and enteral canal (Meckel's diverticulum) is discussed in a review of the intestinal tract (Fig. 40.). When present (2 per cent of cases) and patent (exceedingly rare) this may cause a discharge of intestinal content through the umbilicus. A rudiment of the diverticulum of Meckel may also account for deep entodermal neoplasms in the midline below the umbilicus. In addition this rudiment may give rise to many varieties of internal hernias, strangulations, or even autoanastomoses of the bowel (see Treves⁶¹).

Meckel's
Diverticulum

The umbilicus is a final point of closure in the abdominal wall and within its fibrous ring, which is derived from the

Umbilical Hernias

linea alba, the peritoneum, fascia and skin are closely adherent, while muscle is entirely absent. During development the opening of the umbilical region is of huge size, at one time

FIG. 40. Meckel's diverticulum, the remains of the vitello-intestinal duct, and of the artery to the yolk-sac. (From Treves.)

being equal to one-fourth to one-third the entire length of the embryo. At the sixth week of intrauterine life the navel remains large, is funnel shaped and normally contains a loop of bowel to the apex of which is attached the omphaloenteric duct (duct of yolk sac). Because of these facts hernias at this point might reasonably be expected with higher incidence than is actually found clinically. In rare instances the loop of gut fails to return to the abdomen proper and cases are recorded in which the accoucheur has severed bowel when cutting the cord.⁶² Minor weaknesses of the navel, often observed at birth, tend to close spontaneously as the umbilicus is drawn backward and downward by its ligaments for the body wall continues to grow while the ligaments degenerate from the time when the umbilical cord is ligated and severed. Permanent umbilical weakness may give rise to hernias which vary in size from minute openings admitting but the tip of the little finger to huge masses containing large amounts of omentum, transverse colon, stomach, small bowel, etc. Coughing, straining and lifting, blowing the nose, and performing any act which increases the general pressure within the abdomen tends to aggravate the symptoms and increase the

degree of herniation. The increased size of the abdominal and peritoneal cavities caused by larger hernias leads to hypertrophy of the structures occupying the sac, and to an

FIG. 41. Side view of a case of umbilical hernia. (From Eisendrath's Surgical Diagnosis, Saunders.)

increase in the total amount of intra-abdominal fat (Fig. 41). So great is this increase in substance that the content of the large hernias is often reduced only with the greatest of difficulty and the high mortality following repair of such umbilical masses is thought to be intimately associated with the increased crowding and pressure within the abdomen following closure of the wall.⁶³ (See Intra-abdominal Pressure). So close is the adherence of skin and peritoneum over umbilical hernias

FIG. 42. Various suggested abdominal topographical markings.
 A, After Addison. B, After Mayo-Robson. C, After Anders. D, After Hertzler.

that the sac is almost always opened with the skin incision unless this be carefully made at one side of the mass. The danger of thus accidentally opening peritoneum is obvious.

5. *The Vessels and Nerves of the Abdominal Walls.* These will be dealt with in special chapters.

D. ABDOMINAL TOPOGRAPHY

The object of abdominal topography (Gr. *topos*, place, + *graphe*, a description) is to describe intra-abdominal structures in relation to definite and limited areas on the surface. The exact attainment of this objective is by no means easy. Organs are dealt with which are movable. Tumors and other abnormalities must be described which adhere to no fixed limits. Even the surface on which the measurements must be taken is itself subject to considerable individual and postural

Problems in
Abdominal
Topography

variation. To meet this situation many systems of topographical markings have been advocated. A few of these are illustrated in accompanying figures (Fig. 42). It would, indeed, prove difficult to conceive of any system not already advocated and the many claims and counterclaims relative to the various methods have led to much confusion. A great array of points, lines, circles, triangles, squares, rhomboids, and other figures have been suggested for the surface map, and topography has, in many instances, degenerated from the original high aim of marking upon the surface the location of organs beneath into an attempt to force these organs beneath into imaginary surface compartments, which fail to describe them properly, but prove orderly and convenient to the particular topographical system. The difficulties encountered in attempting to adhere to any single fixed "system" are such that the practical surgeon seems to require some more flexible method for taking his surface measurements and recording his topographical descriptions.

The Nine Abdominal Zones

The abdominal wall, by general acceptance, is divided into nine zones:⁶⁴ an epigastric, an umbilical, and a hypogastric; a right and a left hypochondriac; a right and a left lumbar; and a right and a left inguinal (Fig. 43). Two transverse and two vertical lines are utilized in bounding these zones. The horizontal lines usually employed are: a subcostal line, passing beneath the lower border of the tenth costal cartilages; and an intertubercular line, determined by the iliac tubercles, which mark the highest point of the iliac crests, and are easily found about 2 inches posterior to the anterior superior iliac spines. The two perpendicular lines (lateral vertical lines) pass upward from points on Poupart's ligaments midway between the symphysis pubis and the anterior superior iliac spines, and are parallel with the median plane of the body.

The Transverse Planes

Other transverse planes which have been suggested are illustrated in the accompanying figures (Figs. 43 and 44):

Xiphosternal or xiphoensiform plane

Midepigastric or transpyloric plane

Addison,⁶⁵ after taking careful measurements upon forty bodies, was willing to recognize as constant only five of the many surface landmarks of the anterior body wall. These are: (1) The suprasternal notch; (2) upper border of pubes (the symphysis); (3) right anterior superior spine of the ilium; (4) left anterior superior spine of ilium, and (5) the midpoint of the midline of the body. Addison pointed out that planes depending upon points along the costal margins are unreliable and inconstant in position since the thoracic cage is suspended from the spine and is itself variable in location, i.e., that the subcostal plane might fall so low as to coincide with the umbilical or even with the intertubercular plane. He also noted that existing topographical systems failed to include any plane between the levels of the subcostal and the xiphosternal planes, an area of about 6 inches which contained all of the solid organs and many other important structures of the abdomen. By measurements he found that a plane taken at right angles to the midpoint of the trunk was remarkably constant and valuable. This plane has become known as the midepigastric plane, the line of Addison, or the transpyloric plane, and lies opposite the lower border of the first lumbar vertebra. It is determined by taking the midpoint between the suprasternal notch and the symphysis pubis, or again, that midway between the xiphosternal point and the umbilicus. Corresponding as it does with the level of the first lumbar vertebra, Addison's line marks, roughly, the line of dorsal attachment of the transverse mesocolon which separates the abdominal cavity into its two great divisions, the supracolic and the infracolic. This line marks the transverse bisection of the pylorus (normal) when the stomach is at rest, and is in relation not only with the root of the transverse mesocolon, but also with the kidneys, liver, gall bladder, duodenum, stomach, pancreas and spleen. Thus fixed planes (Fig. 45) overlie the first, third, and fifth lumbar vertebrae; uppermost, the midepigastric plane (Addison's line); lowermost, the intertubercular plane; and midway between these, the central abdominal plane which overlies the third vertebral body.

Addison's Line or
the Midepigastric
Plane

Among the abdominal “points” (Fig. 46) which have been recorded as being of topographical or clinical value are the following:

FIG. 45. “Fixed” transverse planes of the abdomen.

Umbilicus (definitive name; location discussed).

Addison's point (location already given).

Midepigastrie point (same as Addison's point).

FIG. 46. Abdominal topographical "points."

1, Umbilicus. 2, Addison's or midepigastrie point. 3, Midhypogastric point. 4, Sternoxiphoid point. 5, Tip of ensiform cartilage. 6, Robson's point. 7, Lanz' point. 8, McBurney's point. 9, Right costorectal point. 10, Left costorectal point. 11, Mid-Poupart point. 12, Pubic spine. 13, Anterior superior iliac spine. 14, Morris's point. 15, Munro's point. 16, Tender point with acute cholelithiasis.

"Abdominal
Points"

Midhypogastric point, located halfway between the umbilicus and the symphysis pubis in the linea alba (spinal equivalent is variable).

Sternoxiphoid point (definitive name). This lies as a rule on a level with the disc between the ninth and tenth dorsal vertebrae.

Sternoensiform point (same as sternoxiphoid point).

The right costorectal point, located at the junction of the right linea semilunaris with the costal margin. This anatomical point is supposed to mark approximately the location of the fundus of the gall bladder.

The left costorectal point located at the junction of the left linea semilunaris with the costal margin. This marks approximately the spot where the greater curvature of the stomach passes beneath the costal margin.

McBurney's
Point

McBurney's point, described by McBurney⁶⁶ as "located between (in different individuals) $1\frac{1}{2}$ and 2 inches (3 to 5 cm.) of the anterior superior iliac spine on a straight line drawn from that process to the umbilicus." "In every case [of acute appendicitis]," wrote McBurney, "the seat of greatest pain, determined by the pressure of one finger, has been exactly at this point." The point represents the spot at which the terminal filaments of the eleventh thoracic nerve come to the surface as in a whorl (Murphy).

A diagnostic point for acute diseases of the gall bladder (Fig. 47). This is located within 1 inch (different directions with different individuals) of the junction of the midepigastria line with the right costal margin.⁶⁷ This point marks the site at which the anterior branch of the ninth thoracic nerve comes to the surface in a whorl.

Robson's point, located at the inner point of trisection of a line joining the umbilicus and right nipple. Described by Mayo Robson⁶⁸ as "just above and to the right of the umbilicus, where tenderness on pressure exists with diseases of the pancreas."

Munro's point, at the junction of the spinoumbilical line and the right linea semilunaris.⁶⁹ Originally advanced as the

most constant site of the iliocecal valve. It is still retained as a topographical point.

Morris' point, located within 2 inches of the umbilicus

FIG. 47. Tender point for acute cholelithiasis.

- i. With normal or barrel chest.
- ii. With visceroptotic chest.

on the right spinoumbilical line. Believed by Morris⁷⁰ to be a site of tenderness with chronic appendicitis, and present when none exists at the site noted with acute appendicitis (i.e., McBurney's point). Much has been said both for and against the value of the sign in the sense proposed by Morris.

Lanz' point. This is located at the junction of the right linea semilunaris with the interspinous line, and was proposed as a marking for the usual location of the appendix.⁷¹ While this site possesses no clinical and no distinct anatomical significance; it serves as a topographical landmark.

The value of the points of Munro, Morris and Lanz has been questioned, as has the wisdom in retaining these eponyms. On the other hand, McBurney's point has proved of "inestimable value in the diagnosis of acute appendicitis," and its clinical worth is not in the least modified by the proximity of other surface markings. The analagous point (already described) marking the site of tenderness with acute diseases of the gall bladder seems equally constant and valuable.

Abdominal surgeons make use of several triangles located upon the surface of the anterior, lateral and posterior abdominal wall, and upon the thigh. The list includes:

Hesselbach's triangle: base, Poupart's ligament; outer boundary, the deep epigastric artery; inner boundary, linea semilunaris of the same side. This triangle is the site through which direct inguinal hernias protrude.

Surface
Triangles

Scarpa's triangle (femoral or subinguinal triangle): base, Poupart's ligament; inner boundary, adductor longus; outer boundary, the sartorius muscle. It is through the triangle of Scarpa that femoral hernias protrude.

Petit's triangle (lumbar triangle or trigone): (Already bounded, see Drainage through the Hepatorenal Pouch).

Lumbocostoabdominal triangle: Bounded above, by the last rib; medially, by the lateral border of the sacrospinalis muscle; laterally, by the posterior fibers of the internal oblique; floor, formed by the transversus abdominis; roofed by the serratus posterior inferior muscle. This forms a second point of weakness in the posterolateral abdominal wall.

Topographical triangles of Hertzler: This author has described⁷² a series of lines radiating from the umbilicus to the following points on each side: the pubic spine, the iliac tubercle, the tip of the eleventh rib, and the nipple, dividing the surface into eight triangles.

Triangles of cutaneous hyperesthesia. (These triangles represent a method for the practical use in diagnosis of cutaneous hyperesthesia as initiated by certain visceral disorders.) (See chapter on Visceral Neurology.)

1. *The triangle of renal colic:* base, the inner half of Poupart's ligament; outer boundary, a line parallel to the sartorius muscle, extending from the right mid-Poupart point to the inner margin of the thigh; inner boundary, the inner margin of the thigh from the apex of the triangle to the right pubic spine.⁷⁶

The Appendiceal;
Ureteral and
Biliary Triangles

2. *The triangle of biliary colic.* Base, the linea alba from the sternoxiphoid point to the umbilicus; upper boundary, a line from the sternoxiphoid point to the junction of the mid-epigastric plane (Addison's line), with the right midaxillary line; lower boundary, a line from this point (junction of Addison's line and the midaxillary line) to the umbilicus.⁷³

3. *The triangle of acute appendicitis.* Base, a line from the umbilicus to the right pubic spine; lower boundary, a line from the pubic spine to the right iliac tubercle; upper boundary, a line from the right iliac tubercle to the umbilicus.⁷⁴

The surgeon in recording the exact location of tumors and other abnormalities may exercise great freedom and latitude as to topographical method. He is able to accept the advantages of any or all of the fixed systems based upon the authority of individual anatomists, but at the same time need not be hampered by the limitations of any single system. This is true because the surgeon is not seeking, as is the anatomist, surface lines or areas bearing precise relationships to underlying structures constant in location, but is dealing with masses which may appear at any point whatsoever. The common denominator of all topographical systems is their surface landmarks, and by going back to these, the surgeon attains the flexibility which his work demands. He is able at will to strike lines, mark out circles, subtend angles, and create planes, so long as he works from clearly understood landmarks. Moreover, in dealing repeatedly with an individual patient, whose abdominal landmarks will remain approximately the same at different examinations, the surgeon is not limited to the relatively few points or planes which are so exactly fixed as to be universally applicable, hence

A Flexible System
of Topography

serviceable for the anatomist. In this flexible method any landmark may be utilized. In adopting the method, certain useful rules may be stated:

FIG. 48.

FIG. 48. Common sites of pain and pain-radiation with acute abdominal disorders.

St, Stomach. D, Duodenum. P, Pancreas. Sm. I, Small intestine. Lg. I., Large intestine. Bl., Bladder. K., Kidney and ureter. S, Sigmoid colon. G.B., Gall bladder. A-A', Pain of thoracic disease referred to abdomen. B-B', Pain of uterine colic referred to thigh and genitals.

FIG. 49.

FIG. 49. Abdominal organs most often felt during abdominal examination. (Modified from Elsberg.)

1, Margin of liver. 2, Transverse colon. 3, Greater curvature of stomach. 4, Transverse colon. 5, Lumbar vertebrae. 6, Aorta. 7, Iliac arteries (common). 8, Psoas major muscle. 9, Cecum and ascending colon. 10, Lower pole of right kidney. 11, Sigmoid and descending colon.

To create a topographical point: (a) Create two lines which meet at this point (example, the rectocostal point is located at the junction of the outer border of the right rectus sheath

with the costal margin. (b) Pass any line which can be determined by two landmarks through the point and measure along this line to the desired point from either landmark (example, McBurney's point is located from $1\frac{1}{2}$ to 2 inches along the spinoumbilical line).

To create a topographical line: Take the shortest distance between two topographical points.

To create a topographical circle: Take an imaginary circle having a stated radius from any fixed topographical point.

To create a topographical triangle: Join three landmarks, so selected that the boundaries of the triangle (lines joining the landmarks) roughly bound the abnormality in question.

To enclose any topographical figure: Consecutively join any set of landmarks, so selected that the joining lines enclose the abnormality to be described.

Examples of application of flexible method:

1. "This globular, cystic mass lies within a circle having a 2 inch radius and a center 1 inch to the right of the umbilicus" (case proved to be one of mesenteric cyst).

2. "This sausage-shaped mass is 2 inches wide and extends horizontally, lateral to the right mid-Poupart line, from a point 1 inch below the level of the anterior superior iliac spine, to end indefinitely at about 1 inch below the right costal margin" (this case proved to be one of iliocecal tuberculosis).

3. "This pear-shaped mass extends downward for $2\frac{1}{2}$ inches from the right rectocostal point. It can be moved to the right for 2 inches and to the left as far as the midline, describing an arc the concavity of which is directed upward, the obvious point of attachment of the mass being within the right hypochondrium" (case proved to be one of hydrops of the gall bladder).

The accompanying clinical illustrations (Figs. 48, 49) are self-explanatory. They demonstrate with reference to topography, (a) the normal intra-abdominal structures which may most often be palpated through the anterior abdominal wall (Fig. 48); and (b) the usual sites and radiations of certain common abdominal pains (Fig. 49).

EPONYM

CHARLES MCBURNEY

- Eponym:** "McBurney's Point."
Nativity: Roxbury, Massachusetts.
Birth and Death: Born February 17, 1845. Died November 7, 1913.
Connections: 1873. Assistant demonstrator of anatomy at the College of Physicians and Surgeons.
 1874. Attending surgeon, St. Luke's Hospital.
 1880. Assistant surgeon, Bellevue Hospital.
 1882. Lecturer on operative surgery, College of Physicians and Surgeons.
 1886. Consulting surgeon to Presbyterian Hospital; New York Hospital; Hospital for the Ruptured and Crippled.
 1888. Given entire surgical service of Roosevelt Hospital. (Held position for twelve years.)
 1889. Professor of surgery, College of Physicians and Surgeons.
 1892-1895. Vice-president, New York Academy of Medicine. Honorary member of the Royal College of Surgeons (England). Honorary Member of College of Physicians and Surgeons (Phila.).
- Education:** Early education; private schools of Boston.
 Bachelor of Arts, Harvard, 1866.
 Medical degree, College of Physicians and Surgeons, 1870.
 Surgical internship, Bellevue Hospital, New York City.
 Postgraduate study (Europe) subsequent two years.
- Eponym Source:** "Experience with Early Operative Interference in Cases of Disease of the Vermiform Appendix," *New York M. J.*, 50: 676, 1889.
 "Discussion on Appendicitis; Indications for Early Laparotomy." *Tr. M. Soc. N. Y.*, 1891, p. 208.
- Other Writings:** McBurney also wrote concerning the transduodenal method for removing stones from the common bile duct; about "a small transperitoneal incision for the purpose of compression of the common iliac artery by the fingers of an assistant during disarticulation of the hip joint;" contributed to Dennis' System of Surgery, also to the International Textbook of Surgery. He introduced McBurney's hooks for skin grafting and McBurney's tractor for the reduction of fractures at the shoulder joint. It was in 1894 that he proposed the so-called McBurney incision for appendectomy.
- Discussion of Eponym:** McBurney stated that his point indicated the most common site of the base of the appendix. This started a wave of anatomical investigation as to the accuracy of the statement. Notable among the opponents of McBurney were Munro and Lanz. The former found the base of the appendix most often beneath the junction of the spino-umbilical line with the right linea semilunaris (Munro's point);¹ the latter stated that the base of the appendix most often was to be found at the junction of the outer and midthirds of the interspinous line (Lanz' point).²
- Treves was particularly outspoken as to the variation in the position of the appendix and gave little recognition to the value of the single point of McBurney.³
- Murphy, while recognizing the error in assuming that McBurney's point overlay the site of the base of the appendix was still emphatic as to the clinical value of the point-tenderness sign and extensively reviewed possible explanations as to the constancy of the diagnostic evidence.⁴ Among suggested interpretations were, a, that the point was due to an excitation by pressure, of underlying sympathetic ganglia b, that it originated

XVI. DISCUSSION ON APPENDICITIS: THE INDICATIONS FOR EARLY LAPAROTOMY.

By CHARLES MCBURNEY, M.D.,
NEW YORK.

THE title of this paper is one which a very few years ago—not more than four—would have excited the surprise and even the condemnation of many surgical and medical practitioners. The very

I have found the *exact* locality where the greatest sensitiveness to pressure exists to be a valuable means of diagnosis, so that in every case of abdominal pain, not otherwise satisfactorily explained, I make a careful search for it. In the first hours of an attack of appendicitis, it is not enough to compress with the whole hand the region of the iliac fossa. Such pressure will often elicit no more complaint from the patient than pressure of a similar kind made at other parts of the abdomen. But if firm pressure is made with the finger-tip, and especially if the patient be made to cough while such pressure is being exerted, it is invariably easy to determine that the most sensitive point is a definite one in most cases. This point is very accurately in the adult from one and a half to two inches inside of the right anterior superior spinous process of the ilium on a line drawn to the umbilicus. In children it is, in proportion to their size, so much less distant from the spinous process. Occasionally this most sensitive spot will be found a half inch or so nearer the pubes, and sometimes this sensitive area will be larger than usual, but from the first hours of the disease, even up to the end of several days, this sign may be clearly made out in every case. No other acute disease presents this feature. The accuracy of this sign I have demonstrated in every case operated upon by me since I first made the observation. The point described corresponds very accurately in the living subject to the base of the appendix, and for this reason the sign is clearly defined, whether the appendix is long or short, or points up or down. Of course, in late stages of the disease this sign does not usually exist. My friend, Dr. Weir (*The Medical News*, March 1, 1890), commenting upon this observation of mine as to the exact spot of extremest sensitiveness on finger-tip pressure, does not agree with me as to its value, and says: "Furthermore, I have myself found on examination of 18 healthy persons by the above test of McBurney, that in 4 of them decided

Continued from p. 124

from inflamed lymph nodes at this site, c, that the tenderness came from a lymphangitis originating from the appendix and spreading to this area. Murphy believed the real explanation to be that the point of McBurney represented a local area of distribution of cutaneous and subcutaneous nerves which were in reflex connection with afferent stimuli arising from the appendix; he held that the spot indicated by McBurney was that of maximum tenderness regardless of the position of the appendix itself and that the tenderness arose from pressure upon the structures of the body wall itself, not upon structures within the peritoneal cavity beneath.

Many incorrect statements as to the location of McBurney's point are to be found in current surgical textbooks and dictionaries. The most common misstatement is that the point lies half way between the right anterior superior iliac spine and the umbilicus.^{5,6,7,8} It may also be read that the point is always 5 cm.; also 7 cm. from the iliac spine; that it corresponds to the outer margin of the rectus abdominis muscle on the spinoumbilical line, etc.

[125]

SUPPLEMENT: A. J. S., n. s. Vol. VIII, No. 3, p. 729

The fact seems generally to have been ignored that McBurney did not say there was one exact point of maximum tenderness applicable to all individuals but stated that the location of the point was at a variable distance along the spinoumbilical line (within two inches of the anterior superior iliac spine) i.e., while there is no single exact point for all individuals, for *each* individual there is such a single exact point and its location is between one-and-a-half and two inches of the right anterior superior iliac spine on the spino-umbilical line.

Points of Interest:

McBurney was a true sportsman being always fond of outdoor life; during his internship at Bellevue he rowed almost daily upon the East River in a single shell; he was an ardent devotee to golf; was an expert shot and an expert salmon fisherman.

McBurney was among the first to adopt, improve, and simplify aseptic methods such as sterilization of operating materials and instruments by means of the modern steam sterilizer and the use of sterilized gloves in operative work. His fame rests largely with his treatment of appendicitis by the operative method.

By a gift of William J. Sims (1892) the first model elaborate operating pavilion was established for McBurney at Roosevelt Hospital. "His workshop, the Sim's amphitheater of the Roosevelt Hospital was planned by him and built under his direction and was at the time one of the finest surgical amphitheaters in America and a Mecca for American as well as Foreign surgeons."

"He could not have been called a brilliant operator but his lack of hesitation founded on care with which he planned every operation and the thoroughness with which he completed each step before passing to the next resulted in a great saving of time and left the spectator with a profound impression that he had seen a master of art at work; bold, yet a great respecter of tissues, the finished result of his operation left little to be desired" (Peck).

McBurney married Mary Willoughby Weston, Oct. 8, 1874. They had two sons and a daughter. Mrs. McBurney died in 1909.

Dr. McBurney was called to the bedside of President McKinley a few days before his (McKinley's) death.

Due to ill health McBurney retired in 1908 and died at the home of his sister in Brookline, Mass. of heart failure following a hunting trip in Maine (Nov. 7, 1913).

Original Communications.

EXPERIENCE WITH
EARLY OPERATIVE INTERFERENCE IN CASES OF
DISEASE OF THE VERMIFORM APPENDIX.*

By CHARLES MCBURNEY, M.D.,
VISITING SURGEON TO THE ROOSEVELT HOSPITAL.

I VENTURE to introduce once more a subject that has been so ably treated by numerous writers, because I have for some time been devoting my attention in suitable cases to a particular line of treatment, and because I have been fortunate enough to have had recently a considerable number of cases of disease of the appendix under my care.

It is not my intention in this paper to attempt to present the subject of pericecal inflammations in a systematic manner. That has already been done, and very recently, by a large number of writers. I have chosen rather to dwell upon some points in the pathology and treatment of these inflammations, which are beginning to be better understood and which especially interest us all. The fact that inflammatory affections of the vermiform appendix give rise to a considerable number of the so-called pericecal inflammations is now accepted in every part of the medical and surgical world.

This is, I believe, the first recorded case where an acutely inflamed unruptured appendix has been removed full of pus. Who can doubt what the result would have been in this particular case had the cyst ruptured, and the operation been delayed a few hours? Would not the opportunity for recovery have been lost had the advice so often and so recently given been followed—to delay operation until symptoms of spreading peritonitis appeared?

* Read before the New York Surgical Society, November 13, 1889.

The exact locality of the greatest sensitiveness to pressure has seemed to me to be usually one of importance. Whatever may be the position of the healthy appendix as found in the dead-house—and I am well aware that its position when uninflamed varies greatly—I have found in all of my operations that it lay, either thickened, shortened, or adherent, very close to its point of attachment to the cæcum. This, of course, must, in early stages of the disease, determine the seat of greatest pain on pressure. And I believe that in every case the seat of greatest pain, determined by the pressure of one finger, has been very exactly between an inch and a half and two inches from the anterior spinous process of the ilium on a straight line drawn from that process to the umbilicus. This may appear to be an affection of accuracy, but, so far as my experience goes, the observation is correct.*

Before describing the steps of the operation, I refer again to the important aid to diagnosis of which I have already spoken—namely, the ascertaining, by the pressure of a single finger-tip, that the point of greatest tenderness is, in the average adult, almost exactly two inches from the anterior iliac spine, on a line drawn from this process through the umbilicus. Much greater tenderness at this point than at others, taken in connection with the history of the case and the other well-known signs, I look upon as almost pathognomonic of appendicitis. This point indicates the situation of the base of the appendix, where it arises from the cæcum, but does not by any means demonstrate, as one might conclude, that the chief point of disease is there. The abscess, or concretion, or cyst may be at quite a little distance, but the greatest pain, on pressure with one finger, will be felt at the point described.

* Since reading this paper I have carefully observed three other cases. In two the point of pain shown by pressure with one finger was two inches, and in the other an inch and seven eighths from the anterior spine.

EPONYM

JOHANN FRIEDRICH MECKEL

- Eponym:** Meckel's diverticulum. (Remains of the ompholoenteric duct.)
- Nativity:** Halle, Germany.
- Birth; Death:** Born Oct. 17, 1781. Died, Oct. 31, 1833.
- Connections:** Appointed professor of surgery at Halle but promptly exchanged this chair for that of professor of anatomy and physiology.
- Education:** Early education received under his paternal roof. Sent to Magdeburg where he attended the city school.
Studied medicine at Halle and at Göttingen.
Thesis at University of Halle, at the age of twenty-one, "De Conditionibus Cordis Abnormibus."
- Eponym Source:** Received his doctor's degree at Halle in 1802.
Traveled in Italy, Germany, and France where he studied comparative anatomy. (Recalled from his first trip to Vienna by the death of his father 1803.)
"Ueber die Divertikel am Darmkanal." *Arch. f. Physiol.*, 9:421-453, 1809.
Biographie universelle; ancienne et moderne, 27:459.
Manual of Descriptive and Pathological Anatomy. English Ed. London, E. Henderson, 1838.
(Translated to English from the French by A. S. Doane.)
(Translated to French from the German by Jourdan & Breshet.)
(Original German edition was published in 1812.)
- Other Writings:** Abhandlungen aus der Menschlichen und Vergleichender Anatomie und Physiologie. Halle, Hemmerde u. Schwetschke, 1806.
Handbuch der Menschlichen Anatomie Halle u. Berlin 1811.
Editor, Deutsches Archiv. für die Physiologie. Halle u. Berlin 1815-1823.
Editor, Archiv. für Anatomie und Physiologie. Leipzig 1826-1832.
- Discussion of Eponym:** Considerable confusion has arisen regarding credit for this eponym due to the fact that there were two anatomists, grandfather and grandson, with identical names. By many (Stedman,¹ Buck,² Buntz,³ and others⁴) credit has been given to Johann Friedrich Meckel, the elder (1717-1774) but the writings of this anatomist fails to show that he studied or described the diverticulum in question.
The elder Meckel is rightly known for Meckel's ganglion (spheno-palatine); Meckel's cavity (space enclosing the Gasserian ganglion); Meckel's band (portion of anterior ligament binding the malleus to the wall of the tympanic) etc. He also wrote concerning hernias (Tractatus de Morbo Hernioso Congenito Singulari et Complicato Feliciter Curato. Berloini, F. Nicolai, 1772), but included no reference to diverticulum of the terminal ileum.
It was the grandson, Johann Freidrich Meckel, the younger, who wrote extensively concerning the omphalo-mesenteric duct and who distinguished the diverticulum arising from this duct from all other diverticuli of the enteric tract. The younger Meckel described the relation of the omphalo-mesenteric vessels to the diverticulum and the passage of vascular cords from the mesentery of the small bowel to the umbilicus. The diverticulum, however, had been previously described and in 1809 Meckel collected all recorded cases to that date (Ueber Diverticuli; see photostat). Among these few cases were two recorded by his father (Philipp Freidrich Theodor Meckel, 1753-1803) (Thamm de Genitalium sex. Varietatibus. Halae, 1799. Pg. 27, see photostat).
The first reference by a Meckel, then, to a diverticulum of the terminal ilium seems to have been made by Philipp Freidrich Theodor Meckel but it was Johann Freidrich

Meckel the younger who wrote repeatedly and voluminously upon this subject and who devoted many years of study to this anatomical abnormality, hence to whom this eponymic honor chiefly belongs.

This remarkable family of Prussian anatomists included not only father, son, and grandson, but the younger Meckel had also a brother (August Albrecht Meckel, 1790-1829) who became professor of anatomy and forensic medicine at Bern in 1821.

The hobby of the Meckels was a magnificent anatomical museum which was founded by the grandfather, enriched by the father, and enlarged and maintained by the grandson.

Johann Freidrich the younger spent all of his vacations in scientific trips to the principal cities of Europe gathering materials for the museum:

To Italy in 1806, returning by foot all the distance from Florence to Halle.

To Naples in 1811, accompanied by his brother.

To Netherlands, England, and France in 1818.

To Vienna in 1819.

To Paris and Cette in 1821.

To Sicily and Italy in 1824; to Salzburg in 1828; to Venice and Trieste in 1831.

Meckel married in 1810 and his wife was his constant companion in his travels and studies.

When his father (Philipp) who was a highly honored obstetrician as well as an anatomist, was called to the Russian court at St. Petersburg to deliver Empress Marie, the younger Meckel accompanied him.

Meckel died at the age of 52 (1833) from "abdominal hydropsy," having suffered for years from an affection of the liver.

small intestine and continuing into the umbilical sheath. In another still younger fetus I found a similar vessel continuing from the umbilical vesicle throughout the length of the umbilical cord. With this in mind I recently studied a few more embryos and found in older, about ten weeks old, embryos that the intestinal canal had returned to the abdomen and the above long canal as well as the umbilical vesicle had disappeared; but in another I found two embryos of this age (ten weeks) at the usual spot, about one inch above the junction of the colon with the ileum, beside the true appendix a real blind diverticulum, in one fetus it was half a line, in the other one line long; in the first it was placed perpendicularly, in the second, obliquely to the ileum and was only half as wide as the latter. In both embryos the omphalomesenteric vessels were present as fine filaments and in both these diverticuli were found right opposite the umbilicus.

My father found it [diverticulum] associated in one case with hare-lip, cleft palate, and duplex uterus; and found these same abnormalities associated in another case, not with a diverticulum of the intestinal appendage, yet with another malformation which distinctly represented the same abnormality; the vas omphalo-mesenterica which extended from the upper mesenteric artery to the umbilicus."

B. DIFFERENCES DEPENDING ON DEVELOPMENT.

§ 2185. Of all the parts in the abdominal cavity the intestinal canal is formed first; its mode of development and the changes in its situation, form, and volume, present equally remarkable phenomena.*

A. MODE OF DEVELOPMENT.

§ 2186. In respect to the mode of development one part is most intimately connected with the formation of the whole foetus, but particularly with that of the intestinal canal, and most consequently be mentioned first. We mean the umbilical vesicle (*vesicula intestinalis*, a *umbilicalis*). It is a small, more or less rounded pouch, situated between the chorion and the amnion, and is probably much larger in proportion to the foetus the more recent the period of conception. It is even greater than the foetus during the early periods of gestation, and we have reason to think that it is always formed before it. It extends first to the anterior face of the body of the foetus, which rests directly upon it. But gradually and even early in the first month of gestation, it diminishes much, and is situated farther from the

OF THE DIGESTIVE SYSTEM.

375

foetus, so that in the second month it is on the outside of the umbilical cord.

Do the parietes of the umbilical vesicle and the intestinal canal primitively communicate? Several anatomists of great merit think that this communication is demonstrated neither in the foetuses of the mammalia generally nor in that of man in particular. The following facts, however, render this opinion very probable:

1st. The analogy with birds, reptiles, and cartilaginous fishes, to the vitelline membrane of which the umbilical vesicle corresponds perfectly, and in which it is proved that the communication in dispute exists at all periods of fetal existence.

2nd. We sometimes perceive in very young foetuses a canal which goes across the umbilical sheath, from the vesicle to the abdomen, and by which we can at pleasure empty the vesicle of this fluid, and fill it again.

3rd. We always find in the foetus, until the commencement of the fourth month, blood vessels which go from the mesentery to the umbilical vesicle, unite first on this latter, but gradually extend only to the anterior wall of the abdomen, and finally die, and are ruptured or entirely effaced. These are the *omphalo-mesenteric* vessels (*vasa omphalo-mesenterica*), comprehending an artery and a vein, which arise from the mesenteric vessels.

These vessels also exist in birds, where they go to the yolk, proceeding along the vitelline canal.

4th. The intestines are at first very near the umbilical vesicle, and are situated out of the abdomen in the umbilical sheath, which at this period really makes part of the abdominal cavity.

It is not unfrequent, proportionally speaking, to find in the full grown foetus a canal which extends from the intestine to the umbilicus, which opens in this latter place, and is always attended by the *omphalo-mesenteric* vessels.

It is then very probable, though not certain, from all these facts, that the umbilical vesicle and the intestinal canal originally communicate. There are, however, others which really demonstrate the existence of this communication.

Thus we have mentioned above a human foetus five lines long, in which we saw distinctly a filament attached to the umbilical vesicle and extended to the intestine, and we have figured this communication as it exists in foetuses of sheep and cows, since admitted by Bojanus also in the foetuses of sheep.

‡ Hunter, *Anatomische Beschreibung der menschlichen Uterus*, p. 66.
§ Meckel, *Handbuch der pathologischen Anatomie*, vol. I, p. 562.—We have also verified this remark in at least ten foetuses of this age.

¶ Meckel, *Abhandlungen*, 1806, p. 301.—Oken, *Brutzeuge*, 1846, ch. ix.
‡ We have collected, in the first volume of our *Hand der Path. Anatomie*, all the known cases of this anomaly, one of which we observed and described (*Med. Archiv. für die Physiologie*, vol. 12).

§ 2187. Does the intestinal canal always communicate with the umbilical vesicle in one determinate point? What is this point?

First, this canal is continuous with the vesicle by its anterior edge, but very probably the point to which the communication is finally confined, always corresponds to a determinate place, although it may vary in a certain extent.

This place is in the small intestine, and nearer its lower than its upper extremity.

Very probably, there is a period in the existence of the human foetus, when a similar small tubercle exists regularly, after the umbilical vesicle is separated from the intestine. Having found a very large diverticulum attended by the *omphalo-mesenteric* vessels in four human foetuses three months old, which we had occasion to examine at nearly the same time, we have reason to think that the appendix continues regularly until this period, that is, long after the intestinal canal has entered the abdomen. But we now renounce this opinion, although it has been refuted by no one. If a diverticulum really exist for some time as a normal formation, it disappears long before the end of the third month of gestation, since we have seen the cecum in the seventh week, although there was no trace of a diverticulum; whence it follows, that the *omphalo-mesenteric* vessels continue much longer than it. But this circumstance does not prove that the diverticulum never exists normally, or that Oken's opinion of the cecum is correct.

Journal of Anatomy and Physiology, July 1899, 17, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31, 32, 33, 34, 35, 36, 37, 38, 39, 40, 41, 42, 43, 44, 45, 46, 47, 48, 49, 50, 51, 52, 53, 54, 55, 56, 57, 58, 59, 60, 61, 62, 63, 64, 65, 66, 67, 68, 69, 70, 71, 72, 73, 74, 75, 76, 77, 78, 79, 80, 81, 82, 83, 84, 85, 86, 87, 88, 89, 90, 91, 92, 93, 94, 95, 96, 97, 98, 99, 100, 101, 102, 103, 104, 105, 106, 107, 108, 109, 110, 111, 112, 113, 114, 115, 116, 117, 118, 119, 120, 121, 122, 123, 124, 125, 126, 127, 128, 129, 130, 131, 132, 133, 134, 135, 136, 137, 138, 139, 140, 141, 142, 143, 144, 145, 146, 147, 148, 149, 150, 151, 152, 153, 154, 155, 156, 157, 158, 159, 160, 161, 162, 163, 164, 165, 166, 167, 168, 169, 170, 171, 172, 173, 174, 175, 176, 177, 178, 179, 180, 181, 182, 183, 184, 185, 186, 187, 188, 189, 190, 191, 192, 193, 194, 195, 196, 197, 198, 199, 200, 201, 202, 203, 204, 205, 206, 207, 208, 209, 210, 211, 212, 213, 214, 215, 216, 217, 218, 219, 220, 221, 222, 223, 224, 225, 226, 227, 228, 229, 230, 231, 232, 233, 234, 235, 236, 237, 238, 239, 240, 241, 242, 243, 244, 245, 246, 247, 248, 249, 250, 251, 252, 253, 254, 255, 256, 257, 258, 259, 260, 261, 262, 263, 264, 265, 266, 267, 268, 269, 270, 271, 272, 273, 274, 275, 276, 277, 278, 279, 280, 281, 282, 283, 284, 285, 286, 287, 288, 289, 290, 291, 292, 293, 294, 295, 296, 297, 298, 299, 300, 301, 302, 303, 304, 305, 306, 307, 308, 309, 310, 311, 312, 313, 314, 315, 316, 317, 318, 319, 320, 321, 322, 323, 324, 325, 326, 327, 328, 329, 330, 331, 332, 333, 334, 335, 336, 337, 338, 339, 340, 341, 342, 343, 344, 345, 346, 347, 348, 349, 350, 351, 352, 353, 354, 355, 356, 357, 358, 359, 360, 361, 362, 363, 364, 365, 366, 367, 368, 369, 370, 371, 372, 373, 374, 375, 376, 377, 378, 379, 380, 381, 382, 383, 384, 385, 386, 387, 388, 389, 390, 391, 392, 393, 394, 395, 396, 397, 398, 399, 400, 401, 402, 403, 404, 405, 406, 407, 408, 409, 410, 411, 412, 413, 414, 415, 416, 417, 418, 419, 420, 421, 422, 423, 424, 425, 426, 427, 428, 429, 430, 431, 432, 433, 434, 435, 436, 437, 438, 439, 440, 441, 442, 443, 444, 445, 446, 447, 448, 449, 450, 451, 452, 453, 454, 455, 456, 457, 458, 459, 460, 461, 462, 463, 464, 465, 466, 467, 468, 469, 470, 471, 472, 473, 474, 475, 476, 477, 478, 479, 480, 481, 482, 483, 484, 485, 486, 487, 488, 489, 490, 491, 492, 493, 494, 495, 496, 497, 498, 499, 500, 501, 502, 503, 504, 505, 506, 507, 508, 509, 510, 511, 512, 513, 514, 515, 516, 517, 518, 519, 520, 521, 522, 523, 524, 525, 526, 527, 528, 529, 530, 531, 532, 533, 534, 535, 536, 537, 538, 539, 540, 541, 542, 543, 544, 545, 546, 547, 548, 549, 550, 551, 552, 553, 554, 555, 556, 557, 558, 559, 560, 561, 562, 563, 564, 565, 566, 567, 568, 569, 570, 571, 572, 573, 574, 575, 576, 577, 578, 579, 580, 581, 582, 583, 584, 585, 586, 587, 588, 589, 590, 591, 592, 593, 594, 595, 596, 597, 598, 599, 600, 601, 602, 603, 604, 605, 606, 607, 608, 609, 610, 611, 612, 613, 614, 615, 616, 617, 618, 619, 620, 621, 622, 623, 624, 625, 626, 627, 628, 629, 630, 631, 632, 633, 634, 635, 636, 637, 638, 639, 640, 641, 642, 643, 644, 645, 646, 647, 648, 649, 650, 651, 652, 653, 654, 655, 656, 657, 658, 659, 660, 661, 662, 663, 664, 665, 666, 667, 668, 669, 670, 671, 672, 673, 674, 675, 676, 677, 678, 679, 680, 681, 682, 683, 684, 685, 686, 687, 688, 689, 690, 691, 692, 693, 694, 695, 696, 697, 698, 699, 700, 701, 702, 703, 704, 705, 706, 707, 708, 709, 710, 711, 712, 713, 714, 715, 716, 717, 718, 719, 720, 721, 722, 723, 724, 725, 726, 727, 728, 729, 730, 731, 732, 733, 734, 735, 736, 737, 738, 739, 740, 741, 742, 743, 744, 745, 746, 747, 748, 749, 750, 751, 752, 753, 754, 755, 756, 757, 758, 759, 760, 761, 762, 763, 764, 765, 766, 767, 768, 769, 770, 771, 772, 773, 774, 775, 776, 777, 778, 779, 780, 781, 782, 783, 784, 785, 786, 787, 788, 789, 790, 791, 792, 793, 794, 795, 796, 797, 798, 799, 800, 801, 802, 803, 804, 805, 806, 807, 808, 809, 810, 811, 812, 813, 814, 815, 816, 817, 818, 819, 820, 821, 822, 823, 824, 825, 826, 827, 828, 829, 830, 831, 832, 833, 834, 835, 836, 837, 838, 839, 840, 841, 842, 843, 844, 845, 846, 847, 848, 849, 850, 851, 852, 853, 854, 855, 856, 857, 858, 859, 860, 861, 862, 863, 864, 865, 866, 867, 868, 869, 870, 871, 872, 873, 874, 875, 876, 877, 878, 879, 880, 881, 882, 883, 884, 885, 886, 887, 888, 889, 890, 891, 892, 893, 894, 895, 896, 897, 898, 899, 900, 901, 902, 903, 904, 905, 906, 907, 908, 909, 910, 911, 912, 913, 914, 915, 916, 917, 918, 919, 920, 921, 922, 923, 924, 925, 926, 927, 928, 929, 930, 931, 932, 933, 934, 935, 936, 937, 938, 939, 940, 941, 942, 943, 944, 945, 946, 947, 948, 949, 950, 951, 952, 953, 954, 955, 956, 957, 958, 959, 960, 961, 962, 963, 964, 965, 966, 967, 968, 969, 970, 971, 972, 973, 974, 975, 976, 977, 978, 979, 980, 981, 982, 983, 984, 985, 986, 987, 988, 989, 990, 991, 992, 993, 994, 995, 996, 997, 998, 999, 1000.

FIG. 1. ADDISON ON ABDOMINAL VISCERA IN MAN

FIG. 1.—Diagram showing the average position of the landmarks whereby the abdominal regions are limited

FIG. 52A.

ON THE TOPOGRAPHICAL ANATOMY OF ABDOMINAL
VISCERA IN MAN, ESPECIALLY THE GASTRO-IN-
TESTINAL CANAL.¹ PART I. By CHRISTOPHER ADDISON,
M.D., B.S. (Lond.), F.R.C.S., *Professor of Anatomy, University
College, Sheffield.* (PLATES XLIII.-XLIV.)

PURPOSE OF INQUIRY.

With the advance of medical and surgical science, especially with regard to the operations of surgery on the abdomen, the topography of the abdominal viscera becomes of increasing importance.

The method of determining the position of the underlying parts should be as simple as possible, it should be convenient of application, and, withal, having regard to the varying conditions of the abdominal organs, as accurate as can be. One seldom meets with an abdomen which can be called normal in all respects.

The distance from the pubes to the supra-sternal notch is measured by drawing the tape tightly between these points. If the abdomen is convex, the half-way point is marked directly; if concave, the spot directly beneath the mid-point of the tape is taken; and at this point, after a small skin incision, a long steel pin is driven through the abdomen. This marks the level of the upper transverse abdominal line (E.F.).

¹ Read before the Royal Society, December 8, 1898. Communicated by Professor Alexander Macalister, F.R.S.

The average length of the abdominal part of the trunk was 35.8 cm., leaving the manubrium and body of the sternum a total average length of 16.2 cm., or 9.8 per cent. of the total height of the individual. Wright (9) gives the average for males as 9.65 per cent., and for females 9.22 per cent.

The average distance between the transverse lines was 13 cm., or a little over 5 inches. The average distance of the infra-sternal notch¹ above E.F. was 9.8 cm., nearly 4 inches, thus leaving a not too large interval between the body of the sternum and the upper transverse abdominal line. The maximum in this distance was 11.5 cm., and occurred only in 2 cases, and there were only 2 cases in which the distance was less than 8 cm.:—these cases being 7.25 cm. and 7.75 cm. respectively. In such a diversity of subjects, with so different characters of the chest and abdomen, this variation is small.

The line E.F.—Since the mid-point of the distance from the pubes to the supra-sternal notch is taken quite regardless of the condition of the body whether fat or thin, with the abdomen or chest distended or not, the regularity of the position found to be occupied by the line E.F. renders it a most useful line for surface marking.

My purpose, however, in selecting the transverse lines I have described, was simply the obtaining of easily-found, equidistant points for the purpose of measurement; and I was not prepared for the regularity of position in regard to the vertebrae and other structures which, especially, the upper transverse line E.E. has been found to possess. It corresponds almost accurately to the disc between the 1st and 2nd lumbar vertebrae, and cuts the junction of the 8th and 9th costal cartilages at the tip of the 9th.

¹ By the infra-sternal notch is meant the notch at the lower border of the sternum between the two 7th costal cartilages, as it can be felt and located on the surface. By the anterior superior iliac spine is meant that spot where the crest of the ilium, as felt through the skin, ceases, and where Poupart's ligament begins. The xiphoid cartilage is in all cases neglected.

QUESTIONNAIRE

1. What is the general shape of the abdominal cavity?
2. In what diameter is the abdominal cavity most narrow?
3. What is the narrowest point in the anteroposterior diameter of the abdomen?
4. Is the abdominal aorta normally palpable? If so, where?
5. What is the significance of palpation of the abdominal aorta in the epigastric region?
6. What information may the clinician gain when he is able to palpate the abdominal aorta?
7. With what may the palpable abdominal aorta be confused? How may proper differentiations be made?
8. What is the most important matter to determine clinically in regard to abdominal wounds?
9. Explain how intra-abdominal structures may be severely injured without evidences of gross injury to the abdominal wall itself?
10. State, in general, the methods of treatment of injuries to the abdominal wall itself.
11. State what may be done for the patient with a penetrating wound of the abdomen while he awaits operation.
12. Should all cases of perforated wounds of the abdominal wall be operated upon? If so, why? If not, when should expectant treatment be employed?
13. What percentage of gunshot wounds of the abdomen perforate abdominal organs? How many perforate intestinal tract?
14. What are the chief causes of death following perforation of abdominal viscera?
15. What percentage of patients with perforated wounds of the abdomen recover without operative interference?
16. What percentage of cases of gunshot wounds of the abdomen recover following operation? In civil practice? In war practice?
17. What factor, more than any other, influences the mortality rate with perforated abdominal wounds treated by operation?
18. Give the importance of the time factor in operations for abdominal perforations (statistical results in general).
19. Name some of the chief signs and symptoms caused by rupture or perforation of a loop of small bowel.
20. Explain how the following symptoms and signs originate after perforation of bowel: pallor, shoulder pain, hiccough, absence of liver dulness, shifting dulness in the flank, leucocytosis, dyspnea, shock.
21. What is the typical leucocytic curve following a subserous hemorrhage?
22. What are the chief signs and symptoms produced by free fluid in the peritoneal cavity? By free gas?
23. Name some of the evidence leading to a diagnosis of rupture of the bladder.
24. What intra-abdominal conditions are most often suspected after simple strains of the abdominal muscles?
25. In what types of patients are simple muscle strains of the abdominal walls to be especially looked for?
26. What is a desmoid tumor?
27. Give some important points concerning desmoid tumors.
28. How may intra-abdominal tumors and tumors of the abdominal walls be differentiated?
29. What is meant by the "line of congenital anomalies?"
30. Why are congenital abnormalities so frequently found in the midline of the body?
31. Why do congenital anomalies require particular care for their surgical cure?

32. Name ten or more congenital defects which may be found in the midline of the body.
33. What is an epigastric hernia? Varieties of epigastric hernias?
34. What are the symptoms produced by an epigastric hernia?
35. What disease may be most closely simulated by an epigastric hernia?
36. What is the meaning and derivation of the following words: umbilicus, navel, omphalos?
37. Explain the spontaneous cures of umbilical hernias which so often occur during infancy.
38. What are the ligaments of the umbilicus?
39. Explain the central depression of the umbilicus.
40. State some of the reasons why the umbilicus is of special importance to the surgeon.
41. What is pyelephlebitis?
42. What is the caput Medusae? Explain mechanism of its production.
43. What is the origin of the term caput Medusae?
44. What are the nerves found in the umbilical region?
45. What lymph glands are present near the umbilicus?
46. What is the drainage of periumbilical lymphatics?
47. Has the umbilicus a muscle layer? Name the tissues found at the umbilicus.
48. Name the arteries and veins of the umbilical region; from where are the former derived? To where do the latter drain?
49. What is the urachus? The allantois?
50. What is a patent urachus? Its symptoms? Frequency?
51. What is the round ligament of the liver? Its origin?
52. When may the surgeon find it of advantage to sever the round ligament of the liver?
53. What vessels pass through the umbilicus during fetal life?
54. What vestigial band passes at times from the superior mesenteric artery to the umbilicus?
55. What is a Meckel's diverticulum? Its normal incidence?
56. What is the origin of Meckel's diverticulum?
57. Give another name for Meckel's diverticulum.
58. What intra-abdominal pathological conditions are caused by persistent diverticuli?
59. What is the final site of embryonic closure of the anterior body wall?
60. When is herniation of the bowel through the umbilicus a normal condition?
61. What special precaution must be taken in opening the sac of an umbilical hernia?
62. How may small umbilical hernias most easily be detected?
63. What special preoperative precaution is important in dealing with huge umbilical hernias?
64. What is the chief difficulty during operation for large umbilical hernias? What special factor contributes to the high postoperative mortality of this condition?
65. What is meant by topography? Origin of word?
66. What are some of the difficulties encountered in creating a satisfactory system of topographical markings?
67. Name and bound the chief abdominal topographical areas.
68. Give the complete boundaries of the hypochondrium.
69. Name some of the transverse topographical planes used in reference to the abdomen.
70. What abdominal landmarks (external walls) are fixed and constant and which are movable or inconstant?
71. What is Addison's line? The midepigastric plane? The transpyloric plane?
72. With what intra-abdominal structures is Addison's line associated?

73. What vertebra does Addison's line overlie?
74. Name some of the chief abdominal topographical points.
75. Where is McBurney's point? Its significance?
76. Where is Robson's point? Its significance?
77. Where is the point of greatest tenderness with acute diseases of the gall bladder? Why does this point vary with different individuals? How does it vary? How localized?
78. Bound Hesselback's triangle, Petit's triangle, Scarpa's triangle. What is the chief surgical significance of each?
79. What is meant by triangles of cutaneous hyperesthesia? Do they correspond accurately with Head zones or the distribution of peripheral nerves? If not what is their significance and value?
80. What is meant by a "flexible system of topography?"
81. Give examples of the use of such a flexible method.
82. What normal intra-abdominal structures may most frequently be palpated through the anterior abdominal wall?
83. What intra-abdominal masses are most frequent in each of the abdominal topographical zones?
84. What is the most common cause of the pains referred to each of the abdominal topographical zones?

CHRONIC LEG ULCERS

TREATMENT WITH UNNA'S PASTE BOOT

R. A. CUTTING, M.D., PH.D.

NEW ORLEANS, LA.

OF ALL the cases coming under the care of the surgeon perhaps none is more aggravating than the case of chronic leg ulcer. Patients presenting chronic leg ulcers are frequently in rather good health except for their local lesions, and may even feel in no way incapacitated for the regular duties of a more or less active life. Leg ulcers, however, are loathsome lesions, particularly to a person of sensitive disposition, and any relative lack of physical incapacitation shown by the victim may be more than offset by a deleterious effect on his psychological reactions. Patients with incapacitating lesions of far less actual significance than these usually take to bed as a matter of course and are content to remain at rest until such time as nature shall have had a chance to establish the process of repair; patients with chronic leg ulcers, however, tend to become restless when confined to bed and sometimes, taking matters into their own hands, may insist upon ambulatory treatment. Such treatment failing, they tend to drift from one surgeon to another without finding permanent relief, ultimately lose confidence in the medical profession at large, and soon fall easy prey to patent medicines and to various forms of actual quackery.

No single measure can be advocated as a therapeutic panacea for all chronic leg ulcers, since these ulcers vary so widely

in their etiology, but, combined with appropriate accessory therapy, there never has been devised a more efficient treatment than the Unna's paste boot or stocking. Unna's paste is no new substance, having been devised by the Hamburg dermatologist, Paul Unna, who was born in 1850; the method of fashioning this paste into a boot or stocking is also not new, having been used extensively for the purpose in question by many able surgeons both past and present. The author, furthermore, wishes to disclaim all credit for originality in the details of preparing and applying the device, since, in the description of the technic which is subsequently given, he follows a method which has been recognized and practiced with success by many individuals for several years. He feels, however, that the device has not received the general recognition which its value justifies and believes that if the rationale of its use and the method of its preparation were more generally known it would be more frequently provided, and patients consequently would not only be spared much suffering, both physical and mental, but would also be saved many days of economic usefulness.

Complicating the luetic ulcer, the pressure ulcer, and the mycotic ulcer, and tending to reach its acme in the varicose ulcer, is almost invariably a certain degree of local venous stasis and associated tissue

CHRONIC LEG ULCERS

TREATMENT WITH UNNA'S PASTE BOOT

R. A. CUTTING, M.D., PH.D.

NEW ORLEANS, LA.

OF ALL the cases coming under the care of the surgeon perhaps none is more aggravating than the case of chronic leg ulcer. Patients presenting chronic leg ulcers are frequently in rather good health except for their local lesions, and may even feel in no way incapacitated for the regular duties of a more or less active life. Leg ulcers, however, are loathsome lesions, particularly to a person of sensitive disposition, and any relative lack of physical incapacitation shown by the victim may be more than offset by a deleterious effect on his psychological reactions. Patients with incapacitating lesions of far less actual significance than these usually take to bed as a matter of course and are content to remain at rest until such time as nature shall have had a chance to establish the process of repair; patients with chronic leg ulcers, however, tend to become restless when confined to bed and sometimes, taking matters into their own hands, may insist upon ambulatory treatment. Such treatment failing, they tend to drift from one surgeon to another without finding permanent relief, ultimately lose confidence in the medical profession at large, and soon fall easy prey to patent medicines and to various forms of actual quackery.

No single measure can be advocated as a therapeutic panacea for all chronic leg ulcers, since these ulcers vary so widely

in their etiology, but, combined with appropriate accessory therapy, there never has been devised a more efficient treatment than the Unna's paste boot or stocking. Unna's paste is no new substance, having been devised by the Hamburg dermatologist, Paul Unna, who was born in 1850; the method of fashioning this paste into a boot or stocking is also not new, having been used extensively for the purpose in question by many able surgeons both past and present. The author, furthermore, wishes to disclaim all credit for originality in the details of preparing and applying the device, since, in the description of the technic which is subsequently given, he follows a method which has been recognized and practiced with success by many individuals for several years. He feels, however, that the device has not received the general recognition which its value justifies and believes that if the rationale of its use and the method of its preparation were more generally known it would be more frequently provided, and patients consequently would not only be spared much suffering, both physical and mental, but would also be saved many days of economic usefulness.

Complicating the luetic ulcer, the pressure ulcer, and the mycotic ulcer, and tending to reach its acme in the varicose ulcer, is almost invariably a certain degree of local venous stasis and associated tissue

* From the Department of Surgery, Tulane University Medical School, New Orleans, La.
Submitted for publication January 6, 1930.

edema. Malignant ulcers, neuropathic ulcers, and tuberculous ulcers frequently show varying degrees of the same phenomenon. This stasis and edema is not, of course, the exciting cause in the development of any of these lesions, not even the varicose ulcer, which does not develop in the absence of trauma, but when once such lesions have become established the stasis and edema may be sufficient to hinder seriously or even actually to prevent the process of complete repair. The process of repair consists not only of the deposition of new tissue, but of the removal of devitalized and partially autolysed debris. Whenever the venous return from an injured area is so disturbed that this removal of tissue debris is interrupted, the local tissue spaces, the lymphatics and the venous capillaries become clogged, arterial blood is mechanically prevented from reaching the scene, such adjacent tissues as are still vital tend to be deprived of their oxygen supply, and local acidosis and progressive death of tissue ensues. Unless some method of breaking this vicious circle be invoked the best that can be anticipated is a sort of equilibrium between the forces of destruction and the forces of repair in accordance with which alternately now the one and now the other is in the ascendancy, the result being an "indolent" lesion which stubbornly refuses to heal.

If patients with these indolent ulcers can be persuaded to remain in bed for a period of weeks, associated infection of the ulcerating area being controlled meanwhile by the use of hypertonic saline solutions and heat, appropriate accessory treatment also being provided in the form of antisiphilitic treatment for the luetic ulcer, formal operation upon, or the injection of sclerosing solution into varicose veins, in connection with varicose ulcers, the exhibition of massive doses of iodides by mouth in mycotic ulcers (grs. 30-100 t.i.d.), and the like, there are very few cases of chronic leg ulcer which will not eventually proceed to complete healing. General bodily rest

undoubtedly plays some part in the production of this healing, since it allows a concentration, so to speak, of the entire excess of body energy on the affected area, but the local relief of blood and tissue fluid stasis is much more fundamental and important, and is undoubtedly the factor primarily responsible for the good clinical results obtained by the non-ambulatory treatment.

Much has been written on the ambulatory treatment of varicose ulcer, which, of course, is the chronic leg ulcer ordinarily presenting stasis and edema in its most characteristic form, and almost without exception, when reduced to their essentials, the methods involve the application of local mechanical support to the part. The multiplicity of devices used to produce such support, though indicating that none of them perfectly realize the end for which they were designed, nevertheless bear mute testimony to the correctness of the principle involved. Most practitioners of experience have seen certain chronic ulcers heal under the simple expedient of local support by criss-cross adhesive plaster strapping; local elastic pressure as obtained by the use of inflatable rubber bags or balloons, or by the resilient porous rubber sponges of ordinary commerce, should also produce excellent results in certain selected cases. Such devices, however, would seem to have a rather limited scope of usefulness, since the usual indication is for a much more extensive support than they can easily be made to achieve. In relatively few cases is stasis limited to the area of the lesion, and when ulcerations are of considerable extent or, though relatively small, have existed for considerable periods of time, stasis and edema are very apt to be not localized at all but generalized below the knee. The ideal mechanical treatment would therefore seem to be some form of support which would exert gentle and equal pressure over the entire surface of the foot and leg, and which, accordingly, would assure for the ambulatory patient essentially the

same condition which is obtained in the case of the recumbent patient, an extremity devoid of venous and lymph stasis.

The elastic stocking can be made to serve this supportive function fairly well, but is subject to certain almost completely unavoidable disadvantages:

1. When produced in quantity and bought by the patient ready-made elastic stockings are apt to fit poorly; when made to order they are relatively expensive.

2. Even though initially carefully and accurately fitted to the individual patient, the device may very soon become quite worthless, due either to loss of elasticity of the stocking or to actual changes in the shape and size of the limb as the case progresses toward healing.

3. In order to be really effective the stocking must be applied before arising in the morning, i.e. after the recumbent attitude assumed during the night has relieved the affected part of much of its fluid stagnation, and it should be applied after the extremity has been held for a number of minutes nearly vertical in order to facilitate still further reduction in size. Patients of limited intelligence usually fail to appreciate the necessity for attention to this part of the technic, and all patients tend to become careless in observing instructions; occasionally they may even neglect to wear the apparatus for days at a time.

4. The elastic stocking is difficult to keep clean when used in the treatment of an ulcer because of almost unavoidable contamination by secretions, and any attempt to modify the device by cutting holes or windows in it to allow treatment of the ulcer without removing the stocking defeats the entire purpose of the treatment, since it abolishes support over the area where it is most needed.

The elastic roller bandage would be of more value to patients than it is were it not so difficult to apply single-handed and were the patient's intelligence and understanding of the anatomy and physiology involved as complete as that of the medical

attendant who prescribes the mode of treatment. Unfortunately patients advised to use the elastic rolled bandage rarely receive from it the amount of benefit which they might reasonably be expected to enjoy.

The Unna's paste boot is subject to none of these disadvantages, whereas, at the same time, it affords better support than either the elastic stocking or the elastic bandage.

1. The boot is a custom made, built-up affair, which conforms exactly to the shape of the part, because it is applied like a cast. The materials from which the boot is made are relatively inexpensive and can be easily obtained and prepared by almost any practitioner, nearly anywhere, and in the absence of elaborate technical facilities.

2. The boot does not stretch, and when it ceases to fit accurately, due to changes in the shape and size of the part, it can, without compunction, be removed and replaced with another because of its inexpensiveness.

3. Being molded to the part it cannot be replaced by the patient after it has been removed, and, accordingly, the patient is completely under the control of the surgeon at all times; the apparatus functions perfectly regardless of the patient's intelligence or cooperation.

4. Being composed partly of zinc oxide and being relatively impenetrable to secretions, it can be used directly over open ulcers and does not speedily become objectionable through absorption of secretions. When soiled it is not washed and replaced, but cut away and discarded. The Unna's paste boot is never fenestrated, consequently it provides uniform support over the entire extremity.

Unna's paste consists of 4 ingredients (there seems to be no good reason for modifying its composition by the addition of other substances):

| | |
|------------|----------|
| Zinc oxide | 4 parts |
| Gelatin | 4 parts |
| Glycerine | 10 parts |
| Water. | 10 parts |

The formula is easy to remember since it consists of four parts of each of the two solid constituents and ten parts of each of the two liquid constituents.

The only substances entering into the formula which may possibly have some function other than a supportive one are the zinc oxide and the glycerine. Zinc oxide is classified pharmacologically as an astringent; it is possibly a very feeble antiseptic. Inasmuch as it is of little or no value when used by itself on indolent ulcers, the presumption is that its value when used as one of the ingredients of an Unna's paste boot is not dependent upon its pharmacological action. The same line of reasoning may be used for glycerine. Glycerine is classified as a mild antiseptic; it is also somewhat hygroscopic. Its antiseptic properties are so slight, however, that it is used as an ingredient in certain culture media, and its hygroscopic properties apparently have little to do with its usefulness in connection with the Unna's paste boot, as the boot does not become noticeably damp, and secretions even from open ulcers penetrate it only relatively slowly. Furthermore, there seems to be no apparent reason why the combination of zinc oxide and glycerine or indeed the combination of all four ingredients, zinc oxide, gelatin, glycerine and water should act essentially in any except a mechanical manner; certainly the mixture when applied as an ordinary dressing to indolent ulcers produces no such spectacular results as when applied in the form of a well-fitting boot or stocking.

The application of an Unna's paste boot is accordingly believed to accomplish, by a mechanical appliance, for the ambulatory patient exactly the same state of affairs as is accomplished for the recumbent patient by posture. The only advantage which the bed patient has over the ambulatory case with a well-applied Unna's paste boot is general bodily rest, an advantage which is probably of little actual importance in the average case of chronic leg ulcer.

The theoretical value of the method is amply attested by the practical results. Given 2 patients with similar lesions and treated exactly alike except that one is put to bed and kept there while the other is treated with an Unna's paste boot and allowed to go about his daily duties, the latter will improve almost exactly as fast as the other and will be a much more contented and grateful patient.

In applying an Unna's paste boot it is important to observe strictly the following technic, since modifications, however well meant, may make the difference between complete success and utter failure.

Previous to the application of the boot in cases in which open ulcers are present on the lower extremities or in which edema is extreme, a day or two, occasionally several days, of hospitalization with rest in bed and elevation of the part may be desirable in order to relieve edema and control gross infection. Patients with foul ulcers should be put immediately into a hot bath. In the control of infection there is no agent which compares in efficiency with the use of hot, moist compresses of magnesium sulphate solution of about 10 per cent strength. Such a solution is sufficiently hypertonic to prevent maceration of tissues and also to withdraw from the tissues plasma and tissue fluids which in their passage outward serve most efficiently to wash away bacteria and minute particles of decomposing tissue and to bring antibodies into the affected area. Magnesium sulphate itself possesses the well-known property of acting as a local anesthetic when applied to denuded surfaces.

The modern tendency in the treatment of infection is almost entirely away from the use of antiseptic in any case, but in preparing patients for the application of an Unna's paste boot one should particularly avoid antiseptics, since ultimately the entire involved area is to be sealed over.

Patients may be considered ready for the application of the boot whenever the

area surrounding the ulcer no longer shows the classical evidences of inflammation (local heat, redness, swelling, and

should not be heated much above the melting point of the glycerine, since it is subsequently applied directly to the skin

FIG. 1. Method of preliminary draining of venous blood and tissue fluids from foot and leg just prior to application of Unna's paste boot. Part is kept elevated for at least five minutes.

FIG. 2. Proper position of foot and leg during application of boot; foot is held by toes. First turns of bandage at base of toes and just below knee are in place.

tenderness) and when during a period of observation of twenty-four hours the foot and leg are found to undergo but little decrease in size.

At this time and prior to the application of the boot, if the ulcer is a varicose ulcer, the injection of the regional varicose veins may be begun. One or more injections may be conveniently made at this first treatment, the boot being subsequently applied and worn, and at the time of subsequent applications of the boot additional injections may be made.

Having controlled infection to a reasonable extent and having drained the limb of excessive edema, the Unna's paste boot is applied in the following manner:

The ingredients of the Unna's paste are mixed together,* placed in the inner compartment of an ordinary double boiler or rice cooker, and liquefied by means of heat. The proper consistency of the paste just prior to use should be that of thick cream or thin batter, and the mixture

and will require cooling before it can be applied if initially heated to too high a temperature. Furthermore, an excessive amount of heat or unduly prolonged heat interferes with the subsequent "setting" of the paste.

The boot is best applied to the patient after at least one night of rest in bed, before he has been allowed out of bed in the morning, and after at least five minutes of elevation of the part (Fig. 1). If hairy, the patient's foot and leg should receive preliminary shaving. In any case the foot and leg should, of course, be scrupulously clean.

The application proceeds with the patient lying on a table or bed in dorsal decubitus, the leg being flexed upon the thigh and the thigh being flexed upon the abdomen; an attendant steadies the foot by grasping the patient's toes.

The position in which the leg and foot are held prior to and during the application of the boot are most important both from the point of view of the efficacy of the treatment and the patient's subsequent comfort. The flexion of leg on thigh and thigh on abdomen relaxes the calf muscles of the leg and makes possible the applica-

* In case the gelatin to be used is of the solid or "flake" variety, and best in any case, the gelatin and water may be allowed to stand in contact over night; complete liquefaction of the mass with heat on the following morning, addition of the glycerine and then of the zinc oxide, with constant stirring, follow.

tion of a snugly fitting appliance; the dorsiflexion of the foot ensures subsequent comfort in walking and guards

are permitted. At those places at which folding or "reverse turns" would be required, the bandage is simply cut across

FIG. 3. Method of applying Unna's paste with ordinary paint or varnish brush. Gauze roller bandage is held in position ready to cut. Bandage is cut across and started again at different angle in order to avoid making of "reverse turns."

against any tendency to the production of foot-drop.

The first step in the actual application of the boot consists of making a turn and a half of loose-meshed gauze roller bandage about the foot at the base of the toes and another turn and a half about the leg just below the knee. The bandage should be about 2 in. in width. (Fig. 2.)

The Unna's paste, being of the proper consistency and not too hot, is now applied directly to the skin by means of 2 in. paint or varnish brushes from the region of the base of the toes to the bend of the knee, no portion of the surface being exempt, not even open ulcerated areas, the paste being carried almost to, but not quite to the outer edges of the two bands of gauze just previously applied. As soon as the initial layer of Unna's paste has been applied to the skin surface and without undue delay a layer or two of the loose meshed roller bandage is applied directly over it. This layer completely covers the area previously covered by the paste. No folds of roller bandage, or "reversed turns" as they sometimes called,

FIG. 4. Unna's paste boot completed. Note difference in size between two limbs. Circumference of treated foot and leg is much smaller than that of opposite extremity, even disregarding thickness of boot. Support provided by boot is quite evident.

with a pair of scissors and the winding is recommenced at the desired angle. The bandage, like the original layer of Unna's paste, extends from the base of the toes to the bend of the knee and covers the foot and leg, including the heel. A second layer of Unna's paste is now applied over the layer of gauze bandage and over this still another layer of gauze bandage. (Fig. 3.)

In this way the boot is built up to the required thickness; usually about 5 layers of gauze and 7 layers of Unna's paste are required to provide a boot of suitable thickness. The last layer of the boot should consist of Unna's paste, and the entire boot should be allowed to remain

exposed to the air until the surface has dried or "set" to such a point that it is no longer sticky or "tacky" to the touch. The surface of the boot, when almost dry, may conveniently be dusted over with some suitable dusting powder, such as powdered talcum.

The finished boot conforms, of course, precisely to the shape of the foot and leg, because it has been molded thereto; and the Unna's paste, when it has set, provides a support which is moderately elastic, which is not heavy or cumbersome, and which can be worn in complete comfort and without being particularly noticeable when covered by the patient's stockings (Fig. 4).

The patient may be allowed to dress and proceed with his regular duties as soon as the boot has become set and has been properly powdered.

A single application of an Unna's paste boot may suffice only in the simplest cases; usually one or many reapplications are required, the period of time required for complete healing of the ulcer being approximately the same as that which would be required in the recumbent treatment.

The question of the frequency with which Unna's paste boots should be changed is one of individual judgment. In those cases in which no open ulceration is present properly applied boots need not be changed for relatively long periods of time, frequently several months. The principal indications for the removal and reapplication are: (1) soiling of the boot and (2) changes in the extremity such that the boot no longer fits and provides the support for which it was originally intended. In those cases in which extensive areas of ulceration exist and quantities of exudate are continually being discharged the boot may become soggy and require changing at much more frequent intervals, occasionally every three or four days. Perhaps in average cases the boot may be

allowed to remain for a period of three weeks or longer.

The reapplication of an Unna's paste boot is a relatively simple matter. The boot is removed with scissors in the evening, the patient being given a hot bath with plenty of soap and water. The patient is immediately put to bed and remains there until the boot is reapplied on the following morning. The reapplication is made precisely as in the original application.

One of the cardinal principles in the application of the Unna's paste boot and one which can never be disregarded is that no windows or doors shall be cut in it.

Furthermore, one should not discontinue the use of the boot too soon; otherwise the freshly healed areas may promptly break down and ulcerate again. It is better to err on the side of conservatism and continue the treatment for some weeks beyond the time limit dictated by one's first judgment and to reapply the boot subsequently at the first sign of reappearance of the lesion.

The Unna's paste boot, serving as it does a purely mechanical function, cannot be expected to take the place of essential therapy: antisiphilitic treatment, iodides internally, the recognized methods for the treatment of associated varicose veins, wide excision of malignant tissue, and the like.

If the principles of application as previously outlined are strictly followed and suitable accessory treatment is provided, the application of the Unna's paste boot provides a form of treatment which is nothing short of a revelation to one who has tried many of the other practical methods of treatment of chronic leg ulcers. By use of this simple expedient many cases which previously were a source of vexation and disappointment will be transformed to cases providing real satisfaction and pride.

THE SURGICAL ASPECTS OF BILIARY DISEASE*

RUSSELL S. FOWLER, M.D., F.A.C.S.

BROOKLYN, NEW YORK

TO advise appropriate treatment in gall bladder disease it is essential to understand the anatomical and pathological conditions present. It is necessary to estimate the relative importance of symptoms and to correlate them properly with the pathology. We should not think of these cases as gall stone cases for the stones are only incidental to the disease. They are but an expression of the inflammation and not always present. While they may cause symptoms it is the underlying inflammation which must be treated. If during the progress of the disease this inflammation becomes quiescent the stones will no longer give trouble, but so long as the inflammation recurs so long will symptoms persist due in some instances to the stones but in more instances to the inflammation itself and the results of the inflammation,—adhesions, stricture of ducts, perforation, gangrene, peritonitis, cholangitis, liver insufficiency, hepatitis, liver abscess; distant infections from the local focus such as myocarditis, renal insufficiency, pulmonary infections, joint complications; involvement of neighboring organs through extension of the inflammation such as pancreatitis, perforation into the stomach, duodenum or colon, adenitis causing pressure on the common duct either beneath the liver or at or near the ampulla of Vater; carcinoma of the gall bladder following long continued chronic irritation.

Not all cases need operation for not all progress to the stages and results indicated. Many cases become quiescent. It is estimated that of every 100 cases 80 either become quiescent or present such minor disturbances as not to interfere very much with the patient's well being and therefore do not require surgical intervention. Of the remaining 20 there are perhaps 15

in whom operation is distinctly indicated and five in which it is a question of judgment as to whether or not operation should be performed.

It is absolutely essential that the anatomy, physiology and pathological processes involved in the disease and in its complications be clearly understood in order to not only arrive at a correct diagnosis but also, based on that diagnosis, to be able to forecast what will probably be the course of the case and so be able to advise as to treatment. We must correlate the symptoms presented at the time of examination and disclosed by a careful analysis of the history and the physical findings. In no other disease is experienced judgment so necessary. To successfully treat this disease one must not only look at it from the medical but also from the surgical aspect. There is no other disease where differences of opinion are so prevalent. For example, for years patients have been taught to look upon gall stones as the name of their trouble whereas the stones are merely a product of the underlying inflammatory condition. The basic disease is the inflammatory change in the gall bladder wall. As long as the underlying pathological changes persist the formation of stones continues. When we speak of stones we mean not only stones free in the gall bladder but also the calcareous deposits which form on the gall bladder wall.

Before considering what should be the logical treatment in gall bladder disease let us first study how nature sometimes causes the disease to become quiescent.

In the natural course of gall bladder inflammation it sometimes happens that the inflammatory changes progress to a point where they are no longer active. In some cases the gall bladder becomes a

*Delivered under the auspices of the Medical Society of the County of Kings, December 6, 1929. (A Friday afternoon lecture.) Submitted for publication February 20, 1930.

fibrous mass without function the stones being imbedded as foreign bodies. In such a process the more extensive the original inflammation the more fibrous tissue will form and the greater will be the cicatricial shrinkage, the mucosa will be completely destroyed so that the gall bladder becomes a more or less solid cicatricial mass with trabeculae of fibrous tissue tightly enclosing the stones and entirely isolated from the common duct. Nature has done what the surgeon does when he performs a cholecystectomy. In such cases symptoms can no longer be produced by further inflammatory changes in the gall bladder itself. What symptoms do remain are due to adhesions and changes outside of the gall bladder as a result of the formerly active inflammation. Whether symptoms persist from the extrinsic inflammatory changes depends upon the location of such changes. There are not so many gall bladder cases which go on to this final stage with its extensive fibrous tissue changes without, in the course of the disease, producing recurrent disabling symptoms nor can such a final result be relied upon.

A second form of final pathology is hydrops of the gall bladder. A stone remains tightly wedged in the cystic duct or in the neck of the gall bladder. The contents which were in the beginning products of inflammation become sterile, the gall bladder wall becomes overstretched, the mucous lining is destroyed by inflammation, the wall becomes fibrous so that pain is no longer felt nor a sense of pressure. Such a case is proof that even without the removal of the stone a gall bladder inflammation can reach a quiescent stage. It shows that if latency of the inflammation occurs the stone or stones need occasion no anxiety. We rarely, however, see true cases of hydrops. A peculiar thing about hydrops is that because it results in a large and easily palpable tumor patients are quite anxious for an operation on that account and physicians more readily turn such cases over to the surgeon whereas, as a matter of fact, it is not at all necessary to operate on cases of

hydrops. They rarely present symptoms of either pressure or pain. The removal cannot better the patient's condition except to relieve his mind of the anxiety he feels knowing that he has a tumor. I do not think I have operated upon more than half dozen cases of hydrops in some two thousand cases of gall bladder disease and then only when the patient was anxious to be relieved of a tumor though the symptoms therefrom were slight.

Another of Nature's so-called cures is the formation of a fistula between the inflamed gall bladder and some portion of the gastro-intestinal tract, usually the duodenum or the colon. Nature thus not only furnishes a free exit for the normal secretions but also for the products of inflammation.

Still another of Nature's cures is total calcification of the gall bladder, a rare condition.

Such advanced pathological changes are rare. It would be a mistake to wait. Many patients would have no chance to escape an early death. If, as is considered by many, it is unwise to operate in every attack of gall bladder disease it is still just as unwise to wait too long.

In the life history of the disease there are many and often long periods of quiescence.

The above brief resumé of pathology in certain advanced gall bladder cases does show us, however, that the important point is the cure of the inflammation no matter how expedient it may be to remove the stones. If latency could be brought about by diet, medication or treatment other than operation it would of course be preferable. Can latency be brought about by such means or does latency occur irrespective of medical treatment? My impression is that gall bladder disease is a chronic progressive inflammation and that with each attack the gall bladder becomes more and more disabled. The frequency of the attacks, their acuteness and their duration depends upon the severity of the inflammation. For instance, inflammations producing cholestrin stones

are more apt to become latent than other inflammations though the cholestrin stone may lodge in the cystic duct or in the duodenal papilla. In the latter location in the retroduodenal part of the common duct where even in the normal state bacteria are present cholangitis follows very quickly. The removal of a stone so located is therefrom indicated in order to prevent infection. Generally speaking, whether medical treatment or surgical is advisable is according to the grade of the infection and its duration and its effect on the function of the liver.

We have indicated in the opening of this talk that eighty per cent of cases do not require operation for the reason that their symptoms are so slight as not to disable the patient or cause much pain or disturbance. We also indicated that fifteen per cent required operation and of the remaining five per cent it was a question of judgment as to whether operation should be done or medical treatment should be employed. Let us take up very briefly from the surgical standpoint what gall bladder cases may be treated without operation. Medical treatment is indicated in all acute inflammations of the gall bladder showing a tendency to subside with the exception of acute cholecystitis with gangrene, perforation, empyema and cholangitis. Medical treatment is also indicated in all chronic cholecystitis cases which tend toward latency and in hydrops of the gall bladder and in cholecystitis cicatrans not giving pain. Why is medical treatment indicated in these acute and chronic inflammations? In the acute because they are temporary and in both acute and chronic because they are not disabling, do not give the patient much discomfort and do not interfere to any great extent with his enjoyment of life nor his ability to earn his living.

Operation is indicated in acute cholecystitis which does not subside quickly, cholangitis both acute and chronic, gangrene of the gall bladder, perforation of the gall bladder, beginning carcinoma of the gall bladder, in all cases of chronic

cholecystitis, of which there are many forms, in which health is affected over a period of time either through recurring attacks of pain or which cannot be brought to a degree of latency which permits of comfortable digestion and the pursuit of livelihood without too much interference.

There are two classes of cases; those in which operation must be done at once in order to save life and those in which we have time to consider whether operation is advisable or not. In the first it is the physician and surgeon who must throw the weight of their experience in the balance to cause the patient to decide and must insist upon an immediate operation. In the second class there is time in which the case may be studied, discussed with the patient and a mutual decision arrived at in accordance with the degree of interference with the patient's comfort and livelihood. In the first class are the cases of acute cholecystitis not rapidly subsiding, the cases of sero-purulent chronic cholangitis, acute cholangitis, gangrene of the gall bladder and perforation of the gall bladder. In the second class are the cases of beginning gall bladder carcinoma and the cases of chronic cholecystitis in which the patient's comfort and livelihood are being materially affected. I think that all physicians and surgeons can agree with this classification. Certainly in the first group we can all agree as these septic conditions are a direct and immediate menace to life. In the second group it is really up to the patient to give the final decision. He knows and he alone knows how much interference there is with his comfort and livelihood. We can, however, lay before such a patient his probable chances for cure or at least for the decided amelioration of his symptoms by operation and also the mortality of such operation in skillful hands. In many cases it will happen that in spite of recurring disabling symptoms the patient will so dread an operation as to refuse it when the attack has once subsided. Unfortunately for these patients their chances of recovery and of cure following operation are greatly en-

hanced if the operation is done between the attacks at a time when the minimum of inflammation is present, when they feel quite well and free from symptoms. If such patients are operated during an acute attack at a time when they will more rapidly submit to operation on account of their desire for relief of pain we cannot, in many instances, do a radical operation which will almost certainly relieve them, but must content ourselves on account of technical difficulties and dangers in doing a drainage operation thus leaving a gall bladder which in at least twenty-five per cent of the cases gives subsequent trouble. Frequently if it is explained to the patient that an operation between the attacks minimizes the possibility of a second operation the patient will more readily submit. If, however, the patient will only submit during an acute attack then it is again up to the physician to decide whether such an operation should be performed. In this decision he will be aided by a study of the history as to the degree of discomfort and disability. We hesitate to make an emergency operation of such cases because we know how much better a result can be achieved between attacks. Here let me interpolate a word of warning. The inflammation of the acute attacks does not subside as quickly as the subsidence of the symptoms indicates. I have operated three or four weeks after the subsidence of all symptoms and have still found a very considerable amount of inflammation so much so as to make ideal cholecystectomy of more technical difficulty than one would imagine. It is better to wait six weeks after a severe attack before operating if the condition of the patient will permit. It is certainly not sufficient time to operate a few days following an acute attack as is the custom so often in our hospitals. Our objective should be to lower the mortality of gall bladder surgery to a point that will approximate the true mortality of the disease itself and by so doing convince our medical friends of the advisability of early operation.

In the cases in which we advise operation

we base our advice on the degree of discomfort and interference with the patient's pleasures, comfort and livelihood. The symptoms need not necessarily be severe nor necessarily colics, they may be more in the nature of pressure sufficiently painful to aggravate the patient and to keep him from doing his work properly. Many such patients continue to work but their efficiency is impaired. Where patients present symptoms of nagging discomfort they should be advised that operation will cure or at least relieve them to a great extent. As a matter of fact patients presenting these symptoms between their acute attacks become worse and worse the longer they delay and finally must come to operation. The earlier the operation is done the better for them.

The presence or absence of stones is immaterial and should not be used as an argument for or against operation. This is particularly difficult because almost the first thing that the patient asks when he is informed that he has trouble with his gall bladder is "Have I stones?" and the public having been taught for generations by their physicians that it is the stones that give the trouble are apt to submit to operation more readily if they are told they have stones and that these will be given them after the operation. If one uses the argument of stones, which is the wrong argument to use, one would have to carry a collection of stones in one's pocket for emergency use. With increased efficiency in the technique of x-ray examination stones are being shown more frequently and in cases which never had symptoms of gall bladder disease sufficiently severe to require operation. If one were operating for stones one would be operating all the time. If one is operating to increase the patients efficiency and comfort and to lengthen his life one will operate only in accordance with sound indications, not stone indications. The decision to operate should be based on the severity of the symptoms rather than on the pathological changes present. The decision is founded on the history and the physical findings,

sometimes on the one alone and other times on the two considered together. We find gall bladder cases in which operation is imperative and in which there has been no history of more than previous trifling attacks until the present one which is so fulminating as to require immediate operative intervention. In such cases the decision is made upon the physical findings at the time of examination. We have other cases in which the physical findings are negative and in which the decision to operate is based entirely upon the history of repeated disabling attacks. A third group is composed of cases in which the history and physical examination must be considered in conjunction in arriving at a decision. Such cases may have very mild symptoms at the time of examination but their mild symptoms have been repeated so frequently in the past, as shown by the history, as to render operation advisable. In all cases the history is of the utmost value. It may take half an hour or more to get the details of the history while five minutes may be sufficient for the examination itself. Experience allows us to arrive at the causes of the different forms of jaundice, for instance, without the necessity of making all kinds of examinations of the urine, feces and blood. We should endeavor to make not only a clinical but also a pathological anatomical diagnosis. This is often though not always possible through study of the history alone experience making our diagnosis quite certain. Physical examination is not so certain. An educated sense of touch, however, can tell us much; we should learn to see with the ends of our fingers, to correlate the history and physical examination. In ninety per cent. of our cases we should arrive at a pathological anatomical diagnosis before opening the abdominal cavity. Such diagnosis can only be made after a study of hundreds of histories in connection with the operative findings. The physician should do this as well as the surgeon. There is no other way in which gall bladder disease can be learned. He

must attend operations and autopsies and learn to correlate the history and the physical examination with the findings. It is easy to make a diagnosis of gall bladder disease. It is not easy to diagnose the variety and extent of the disease, and above all it is not easy, unless one has studied the subject in the above manner, to decide which case requires operation and which may be treated medically. We see cases which have been treated medically and which present at operation fulminating inflammation and cases which present chronic empyema both of which conditions should have been sent to the surgeon long before. A proper knowledge of gall bladder disease would enable the physician to send such cases to the surgeon at a time when operation is practically without danger. Cases discussed by the physician and the surgeon will do much to help them both to properly care for this disease.

The presence or absence of symptoms cannot always be properly interpreted. There are cases which have no tenderness at all in the region of the gall bladder and yet at operation the interior of the gall bladder shows marked acute inflammatory changes which would undoubtedly have led, in a few days, to perforation. Nor can clinical symptoms always be depended upon. Many cases of empyema show slight or no fever; many stones in the common duct show no jaundice.

Pain is one of the indications for operation more so when recurring repeatedly and becoming more constant and especially when of a pressing character. It is usually the pain which causes the patient to consult the surgeon. More or less constant pain is practically always a symptom of chronic inflammation, but chronic inflammation does not always give pain. Some cases without pain show empyema of the gall bladder and some chronic cholangitis, in both of which operation is indicated.

Jaundice and enlargement of the liver are indications for operation just as pain is when the conditions are of a chronic character. In spite of the extensive studies

in gall bladder pathology there are physicians who cannot understand how the patient can have gall stones without jaundice. An acute attack of jaundice is not an indication for operation unless it appears coincidently with symptoms of acute inflammation. In the latter case the jaundice depends on involvement of the lymph glands around the head of the pancreas and along the common duct. In the majority of cases with acute jaundice the jaundice is caused by pressure on the common duct or acute closure of the duct. When a sudden closure of the duct is caused by stone there is an accompanying acute cholelithiasis. If the inflammation goes on to suppuration or becomes chronic jaundice will persist. In such cases operation should not be delayed. Early operation in cases of chronic closure of the common duct shows a mortality of three to four per cent; delay increases the danger threefold. In chronic cholangitis jaundice and colicky pain may disappear and chills and vomiting occur. The temperature may range as high as 104. Operation should not be delayed. It is useless to wait for the obstruction to be overcome by other than operative measures. There are occasionally reported cases with chronic closure of the common duct who have recovered without an operation. The quiescent period can only be temporary; the inflammation has subsided and the stone is resting. Sometimes the stone passes through the papilla or finds its way into a neighboring organ through ulceration. Though this occurs in a few cases and is Nature's attempt to cure it is unsafe to wait for such an event. Early operation gives a much lower mortality.

Some physicians rely upon the physical examination to give indications for operation. This is not always satisfactory; the history is what we depend upon most though in certain cases the physical examination is of decided value as in the following instances:

1st. An enlarged gall bladder not sensitive to pressure without jaundice. Is opera-

tion indicated? No. Why? Because such a condition is almost always a sterile hydrops of the gall bladder which is harmless.

2nd. An enlarged not sensitive gall bladder with jaundice. Should such a case be operated upon? Yes. Why? Because such a physical finding is usually carcinoma of the gall bladder, duct or pancreas, or a chronic pancreatitis. In such cases operation (cholecystenterostomy or cholecystgastrostomy) can in the case of cancer often relieve and if the case is one of chronic pancreatitis the operation may really prove curative.

3rd. An enlarged gall bladder with slight jaundice and with the gall bladder slightly sensitive to pressure. Should operation be done? Yes. Why? Because as in the second instance cited such a condition is usually one of carcinoma or chronic pancreatitis.

4th. A *very* tender and well circumscribed enlargement of the gall bladder with little or no jaundice. Should operation be done? Yes. Because such physical findings point to an inflammatory process of a seropurulent or purulent nature. Operation in such cases is not so urgent but still an operation must be done. Done early the mortality in such cases is about three per cent. and the mortality is increased by waiting. The operation is not so emergent as in:

5th. A case presenting the same symptoms and clinical appearance as are present in gangrenous appendicitis except as to the location of the pain which is in the gall bladder region and in which there may be only a little resistance over the gall bladder. Should operation be done in such a case? Yes. Why? Because these symptoms are those of gangrenous inflammation and while no tumor can be felt either because of the thickness of the abdominal wall, the location of the gall bladder under the ribs, or the primary rigidity of the abdominal wall yet the sudden subsidence of the local symptoms leads us to suspect gangrene or perforation. Here the clinical appearance does not at all denote the

serious pathological changes but operation is most imperative. Usually gangrenous cholecystitis is readily diagnosed and should always be treated in the same manner as gangrenous appendicitis, acute pancreatitis or strangulated hernia, that is, by immediate operation.

6th. Cases in which sensitiveness to pressure in the gall bladder region persists; not only the sensitiveness felt by the patient but also the increased sensitiveness caused by the examining hand. This is very important. Should operation be advised? Yes. Why? Persistent sensitiveness is the main indication for operation. The area of sensitiveness varies according to the location of the gall bladder. Cases in which the gall bladder can be mapped out and in which not only it is sensitive but the surrounding peritoneum is sensitive and in which the sensitiveness persists are cases of acute purulent cholecystitis. The differentiation between this and perforated duodenal ulcer is largely made on the area of sensitiveness but such a differentiation is not necessary. Both conditions require immediate operative interference.

7th. Cases complaining of continuous pressure in the gall bladder region with a tender gall bladder, the patient not being able to attend to his daily duties and deprived of enjoyment of life through the continuance of the pain. Should operation be done? Yes. Why? Because such a condition is disabling. When we operate we find changes in the gall bladder which can only be corrected by operation.

8th. Cases where jaundice appears, in which there is one chill and rise of temperature but in which a gall bladder tumor is not present and in which sensitiveness is lacking. Should operation be done? No. Why? Because such a condition may be one of simple cholecystitis which may rapidly subside, but if fever and chill recur or if persistent sensitiveness be added operation should be advised at once.

9th. Cases showing enlargement of the liver. This of itself is not an indication for

operation but a liver progressively increasing in size with fever and severe constitutional disturbances, with or without jaundice, in a patient who has a history of gall bladder disease is an indication. These physical signs and symptoms point to suppurative cholangitis, a disease in which medical treatment is only palliative but in which early operation, free drainage of the infection by choledochostomy, is the only means by which life may be saved. To delay is fatal. Medical measures, sodium salicylate combined with urotropin, are helpful as adjuvants to surgery. The subject of enlargement of the liver in relation to gall bladder disease requires more consideration than is allowed for in the time at our disposal.

10th. Cases showing enlargement of the pancreas in the course of gall bladder disease but in which the gall bladder is not palpable. Should such a case be operated upon? Yes. Why? Such a case is either one of acute inflammation of the gall bladder with subsequent involvement of the pancreas through the connecting lymph glands or a case of cholangitis, both conditions which demand operation. It must be remembered that pancreatic involvement occurs in about one-half of the cases of cholangitis and in about ten per cent. of cholecystitis cases, though in the latter the pancreatitis may only be discovered at operation.

11th. Cases presenting jaundice. When is jaundice an indication for operation and when does it contraindicate operation? Patients with jaundice who show a fairly wide spread bleeding under the skin and who show acidosis should not be operated upon without proper medical preparation. Slight jaundice which may be from pressure of lymphatic glands along the common duct or about the head of the pancreas or beneath the liver does not increase the danger of operation. Jaundice caused by chronic closure of the common duct operated upon early does not materially increase the danger. In this class of cases we should not wait until slight jaundice

progresses to severe jaundice with its bad effects upon all tissues and organs including the blood. It is quite important that we operate at the right time. Many cases are brought to us late in the course of their jaundice. It has long been taught that to operate during jaundice is extremely dangerous so that the patient is not apt to consult the surgeon unless urged to do so by his physician, thus delaying operation until it is too late. Unfortunately cases of jaundice are rather difficult to prognosticate. Often catarrhal jaundice with its accompanying gastro-duodenal catarrh and its mucous plug in the common duct is confused with chronic pancreatitis, tumor of the head of the pancreas, a tumor growing retroperitoneally either involving or pressing upon the common duct secondarily or with stone in the common duct. The usual course of catarrhal jaundice is six weeks. Under modern medical treatment (duodenal drainage) the course of the disease is shortened one half. If a case has been diagnosed and is being treated as one of catarrhal jaundice and in which no other diagnosis persists with jaundice beyond the three to six week period it should be operated. Catarrhal jaundice is jaundice free from pain. In such cases duodenal drainage is advisable to shorten the period of the jaundice. When pain is present or when pain has been part of the previous history or when pain develops during the course of the jaundice operation should be done immediately. The earlier the operation is done in the course of the jaundice the safer the operation.

The size of the gall bladder is of value in differentiating between pressure of malignant disease and stone in the common duct as a cause for the jaundice. If we find the gall-bladder distended and jaundice present we make a provisional diagnosis of carcinoma. We are not, however, always able to palpate the gall bladder on account of other factors so that while the presence of a palpable distended gall bladder is of value its absence is not of such important

diagnostic significance. In catarrhal jaundice the gall bladder is flabby and not enlarged.

Frequently jaundice only lasts a few days. In such cases there is history of pain followed by sudden jaundice rapidly clearing up. Here we have to do with a stone which has passed from the gall bladder to the duodenum, though in certain cases it may remain in the common duct quiescent for a while only to cause trouble later. One such attack is not sufficient indication for operation. Frequently such cases go for years without subsequent trouble. When the attacks are repeated and disabling, however, operation should be done.

Before leaving the subject of jaundice let me impress upon you that jaundice is not a necessary symptom of gall bladder disease. The majority of cases never have jaundice. When present, except when evanescent, operation should be done early no matter whether the jaundice is caused by an acute lymphadenitis, by choledochitis, by stone, by sclerotic pancreatitis or by carcinoma of the pancreas or common duct. No matter how skillful we are in diagnosis we cannot always be sure of the exact pathological conditions present and to delay operation in the presence of jaundice, unless the case is one of catarrhal jaundice or familial jaundice or infectious jaundice (Weil's disease) or hemolytic jaundice, is to invite disaster. Jaundice persisting following a slight attack of cholecystitis should be an indication for immediate operation. Jaundice is only one of the symptoms. It may accompany acute cholecystitis as well as chronic cholangitis. The depth of the jaundice is of value in arriving at a probable diagnosis. Jaundice caused by stone is apt to be deeper and more bronze than that caused by pancreatitis which is lighter and more yellowish green. Variable jaundice with a gall bladder which is not palpable makes a diagnosis of intermittent closure of the common duct by movable stone plus inflammation probable. Painful enlargement of the gall bladder with jaundice makes a

diagnosis of cholecystitis with lymphadenitis probable. Painful enlargement of the gall bladder which rapidly disappears suggests a diagnosis of cholecystitis which has drained through the common duct. Jaundice coming on after an acute attack in which the enlargement of the gall bladder persists leads to a diagnosis of an extension to the lymph glands along the common duct. In all these conditions operation is indicated. Allow me to repeat that jaundice is not a contraindication to operation but on the contrary often is an indication for immediate operation.

Given a case in which a tumor is plainly felt in the neighborhood of the gall bladder and in which ascites and deep jaundice are present the probable diagnosis is inoperable carcinoma, yet I have found on exploring such cases that occasionally the physical signs are caused by sclerotic changes in the head of the pancreas with lymphadenitis about the pancreas and along the common duct associated with an old chronic gall bladder with adhesions, the whole pathology being due to gall bladder infection. Such cases should not be denied the chances afforded for their greater comfort by operation, they should have the benefit of an exploration.

Occasionally carcinoma is diagnosed in cases of common duct stone causing intermittent jaundice and finally deep jaundice with cachexia. Such cases should also have the benefit of exploratory operation.

Conclusions. If the disease is considered as a focal infection the indications for the removal of such a source of infection are the same as for removal of an infected focus elsewhere i.e., infected teeth, tonsils, appendix, etc. Some physicians, however, think that a fulminating inflammation or a chronic closure of the common duct or a perforation of the gall bladder or a case where the pain is very severe and continuous, that such conditions are the only indications for operation, that is, that there are only three distinct indications. First—empyema; second—closure of the common duct;

third—such cases which in between attacks never feel well. Other surgeons believe that not only cases of the above type should be operated but that practically all cases showing chronic inflammation of the gall bladder should have the gall bladder removed. They believe that the gall bladder should be removed before the inflammation extends to the ducts. In such cases operated early before common duct involvement, the operation is comparatively simple and certainly less dangerous, while if delayed until the common duct is involved the operation is more complicated and certainly more dangerous. Other surgeons and many physicians maintain that early operation is not wise. Be all this as it may there is only one radical cure, that is, removal of the gall bladder and if necessary drainage of the common duct. Removal of the gall bladder, however, is not always possible. The inflammation may be so acute as to render cholecystectomy technically unsafe. This point can only be determined at the operation itself. Cholecystectomy should never be promised before operating upon an acute case. It should be stated that if the gall bladder can safely be removed this will be done. This statement is made here because so many patients now demand removal of their gall bladders believing that even with pathology advanced beyond the gall bladder itself that such an operation is curative. In this they are of course wrong because, while cholecystectomy before the disease has advanced beyond the gall bladder is curative in ninety-four per cent of cases, after the disease has extended outside the gall bladder and involved the common duct, pancreas, liver and neighboring organs through adhesions, and has caused atony of the small and large intestine and a weakened heart muscle through years of chronic infection, as well as impaired kidneys and a host of other nervous infective and metabolic changes, cholecystectomy cannot be followed by a cure of all the complications caused through delay in operating.

TREATMENT OF ACUTE APPENDICITIS*

EDWARD T. CROSSAN, M.D.

PHILADELPHIA, PA.

SO MUCH has been written and preached about the "unnecessarily high death rate" in acute appendicitis being due to the delay of the patients, surgeons have subconsciously adopted the idea that operative mortalities in this disease require no other explanation. The increase of the death rate noted by Eliason and Ferguson¹ cannot be altogether due to the negligence of the public; the propaganda must have had some effect. To castigate the public with the hope of improving conditions is a negative procedure, in fact, it is pharisaical because there still exist surgeons who permit cases of acute appendicitis "to ride" until a time convenient for operation. Amelioration of mortality figures will occur when surgeons, particularly part-time surgeons, realize that even in the complicated cases recovery is the expected outcome.

From many clinics throughout the country there are reported results which show that the mortality rate can be held to a surprisingly low figure. To those who will argue that even this percentage is too high, let it be answered that the death rate in almost every disease is unnecessarily high.

In the last 203 cases² operated on in this clinic there were 5 deaths, a mortality rate of 2.5 per cent. Two of the deaths were not directly attributable to this disease: one patient, an appendiceal abscess case of five weeks' duration before admission, died from a severe reaction a few hours after a blood transfusion; the other patient, operated on for a gangrenous appendix, died in diabetic coma. The efficiency of the treatment in this group in reality is represented by the figures of 3 deaths in 201 cases, or a mortality of 1.5 per cent; all 3 deaths occurred from peritonitis. Of the 201 cases, as shown in the accompanying table, there were 33 cases of abscess,³ 36 cases of peritonitis, 25 cases of gangrene,⁴ and 107 markedly acute cases.⁵

Our success is not due to any new technic. There is no new technic, nor modification of technic that remains to be described unless it be along the lines of chemotherapy. We attribute our good results to the observation of the following fundamentals, viz: (1) an operation performed as soon as possible; (2) the use of an incision which does the least damage to anatomical structures and which, in the presence of complications, will (a) give adequate exposure through the smallest wound, (b) reduce the dangers of hernia and (c) prevent contamination of the peritoneal cavity in abscess cases; (3) efficient treatment of the focus of infection; (4) enough drainage material and not too much; (5) detailed postoperative care.

THE TIME TO OPERATE

In speaking of the necessity for immediate operation in the simple cases (i.e. not abscess or peritonitis), Dr. Ashhurst⁶ has stated that "no one can tell from one hour till the next what will happen as long as an acutely inflamed appendix remains within the belly." Amplification of this statement is unnecessary. In this clinic we extend the generally observed rule to include those cases in which there is doubt whether the symptoms are due to appendicitis or salpingitis, in other words, we occasionally operate for diagnosis. If the diagnosis proves to be acute salpingitis, the operative procedures are limited to the appendix.

We feel that abscess cases are as much in need of emergency treatment as the simple cases. It may be true, as stated in a recent textbook of surgery, that 90 per cent of all abscesses will absorb. However, in our experience the walls of many abscesses are made up of coils of intestine glued together by fibrin, a very weak bulwark against peritoneal contamination. Procrastination does not improve

*From the Clinic of Dr. Astley P. C. Ashhurst, Episcopal Hospital, Philadelphia, Pa.

Submitted for publication August 13, 1929.

the patient's condition. Delay does increase the dangers of pyelephlebitis, fecal fistulae and peritonitis.

In peritonitis cases, procrastination assumes an important rôle in the treatment. From the surgeons of the preceding generation it was learned that to operate on the very sick cases meant a frightful mortality and because of this there was developed the treatment with which are associated the names of Fowler, Ochsner, Murphy and Alonzo Clark. Like most other surgeons we depend to a great extent on the condition of the abdomen to determine whether or not a patient requires immediate operation. When rigidity exceeds distention we operate, and when there is decided distention we resort to the expectant treatment. Eight out of the 36 peritonitis cases shown in the table were too ill for operation when admitted; out of this number one died. The one death occurred in a child, which brings up for discussion the rule that all peritonitis cases in children should be operated on because children "stand peritonitis badly." Our experience does not agree with this statement. In the group of 8 already noted, 2 of the recoveries were in children, and furthermore, in the fatal case the peritonitis was subsiding when on the third day the child suddenly became distended, probably due to a re-infection from the rupture of an abscess between intestinal coils.

THE INCISION

Thirty-five years ago, McBurney described an incision which seemed to be ideal in that anatomical structures were preserved and that the approach was close to the site of the appendix. Before long it was recognized that the incision offered insufficient exposure for the difficult cases, and as a result there came into existence: (1) Wier's modification, a prolongation inwards from the lower end of the McBurney incision, and (2) Elliot's more direct method of an initial transverse incision.⁷ Elliot's incision did not meet with the approval of his confreres, and, like Wier's incision, seems to have fallen

into disuse after the author's death. On October 2, 1905, before the Philadelphia Academy of Surgery G. G. Davis⁸ again described the transverse incision with the modification of retraction of the rectus towards the midline: in this communication Davis gives credit to Elliot for the original idea. Subsequently, but before Davis' article was published, A. A. Rockey⁹ described the same incision.

The incision is placed transversely at the level of the anterior superior spine with the center over the semilunar line (Fig. 1) and is 5 or 6 cm. in length. The aponeurosis of the external oblique is divided in the same direction as the skin wound (Fig. 2): in this detail the incision is not as ideal as that of McBurney, because it cuts across the fibers of the aponeurosis which run in an oblique direction. At this time it will be noted that the fibers of the aponeurosis pass half way over the rectus before they fuse with the anterior sheath (Fig. 2). After splitting the external oblique muscle, the internal oblique and the anterior sheath of the rectus come into view (Fig. 2). The next step is division of the anterior sheath of the rectus transversely and retracting the rectus muscle towards the midline (Fig. 3). From this point there are two possible variations, viz.: (1) opening the peritoneal cavity in the gap left by the displaced rectus, hooking up the abdominal wall on the left index finger inserted inside the peritoneal cavity and splitting the internal oblique and transversalis muscles transversely outwards with scissors, or, (2) dividing the semilunar line with scalpel and blunt separation of the muscle fibers (Fig. 3). Either one of the variations preserves the nerves which pass transversely inward to the rectus muscle.

I have used this incision for fifteen years or more. Like Rockey,¹⁰ I believe that once this incision has "been understandingly practised" it will never be abandoned. With this approach the incision need not be any longer than the McBurney incision, for difficult cases the incision can be extended inwards or outwards, and in the

event that the diagnosis proves to be a ruptured ovarian cyst, or a twisted cyst, or an intussusception, the condition can be

from unguarded movements. When the incision has been extended to the full length, the abscess cavity lies in plain

FIG. 1. Transverse incision for appendectomy.

adequately treated through this wound. However, the most decided advantages of the incision are experienced in the treatment of the complicated cases.

In abscess cases the peritoneal cavity can be opened to the inner side of the mass by dividing the peritoneum in the gap left by the displaced rectus, thus at the outset avoiding any contamination of the peritoneal cavity. Through this opening the abscess is surrounded by packs before extending the wound outwards, thereby protecting against any rupture of pus

FIG. 2. External oblique divided, exposing internal oblique and anterior sheath of rectus with rectus muscle showing through sheath.

view and in most all of the cases the appendix can be removed without fear of disseminating pus.

In the peritonitis cases the incision need only be 3 or 4 cm. and is placed directly over the appendiceal region. If there be one place that the trite saying "better measure for a belt than a coffin" is not applicable, it is in these peritonitis cases. The larger the wound, the greater are the number of the lymphatics that are opened, and the greater is the absorption of toxins. The larger the wound, the more extensive is the wound infection and again the greater is the absorption of toxins. The proximity of the wound to the appendix nullifies the arguments about the dangers of removal of the appendix in this complication.

In closing the wound, particular attention should be given to the sutures at the semilunar line because this is the weak point in the incision as shown in the diagram attached in Figure 4. Also, the drainage should be taken through the outer angle of the incision for the reason noted. With the latter precaution there will be a lower incidence of herniae because the contractions of the transverse muscles on the walls of the drainage tract have a tendency to close the gap in the tissues.

TREATMENT OF THE APPENDIX

As has been previously indicated, with the transverse incision and a packing-off

FIG. 3. Internal oblique and transverse muscle being split outwards by handle of scalpel. (A) External oblique (B) internal oblique (C) rectus muscle retracted outwards.

of the abdominal cavity, we have been able to remove the appendix in most of the abscess cases: in the group here reported there were 28 appendectomies (primary) in the 33 cases of abscess. There was not a single fatality in the 33 appendiceal abscesses. No one of the 5 patients who had drainage alone was permitted to leave the hospital until the stump of the appendix was removed. To permit these patients to leave the hospital without a secondary appendectomy frequently means that they will have a prolonged siege of drainage, and subjects them to another attack of appendicitis or to the development of another appendiceal abscess.¹¹

The appendix was removed at the primary operation in all 28 cases of peritonitis which were operated on soon after admission. In the 8 cases treated by the expectant method, the appendix was removed in 7 at the time the post-Ochsner abscess

was drained; the one case in which the appendix was not removed was the child who died from a re-infection. It has always

FIG. 4. Diagrammatic cross section of abdominal wall at level of anterior superior spine. Arrow points to semilunar line.

been our belief that drainage alone in these cases is not a sound practice because, if the patient is too ill to resist a procedure which requires only two or three additional minutes, which opens no lymphatics in the appendiceal region, but which does shut off the focus of infection, he is too ill to be exposed to additional absorption of toxins through the lymphatics of the abdominal incision. There were two deaths in the 28 cases we treated in this manner, or a mortality of 7 per cent.

DRAINAGE

For the abscess cases, and for the cases of extensive gangrene such as the 25 noted in Table I, we use cigarette drains:

TABLE I

| | TOTAL CASES—201. | DEATHS—3. | MORTALITY 1.5 PER CENT | |
|------------------------------------|------------------|-----------|---------------------------|--|
| | Cases | Deaths | Mortality, per cent | |
| Acute appendicitis (simple)..... | 107 | 0 | 0 | |
| Appendicitis with abscess..... | 33 | 0 | 0 | |
| Appendicitis with peritonitis..... | 36 | 3 | 8.3 | |
| Appendicitis gangrenous .. | 25 | 0 | 0 | |
| Total..... | 201 | 3 | 1.5 | |

usually two drains for the abscess cases placed in the abscess cavity; and one drain only in the gangrene cases, placed in the pelvis. In the abscess cases, one drain is removed in forty-eight hours; the second drain is shortened on the fourth day and the shortening continued until the seventh

day when the stump of the wick is entirely removed. In the gangrene cases the drain is removed, if there be no infection, in forty-eight or seventy-two hours.

For the peritonitis cases we still use the glass tube which was originally used by Koeberle and modified to the present form by Keith in 1866. This procedure is considered obsolete by most surgeons. To us it still has the advantages that it maintains a rigid canal through which the pus can be aspirated, and, furthermore, it is a signal in our hospital that this patient is very dangerously ill and requires a nurse day and night until the drain is removed. Above all with the glass tube, there is less tendency to the formation of adhesions and the occurrence of postoperative obstruction. The glass tube is passed into the pelvis, and behind the tube there is placed a cigarette drain to the same area in order to make use of capillarity. As soon as the purulent discharge changes to a serous character, or about forty-eight hours after operation, the glass tube and the cigarette drain are replaced by a rubber tube which is shortened on the fourth day and removed on the seventh.

There has been considerable discussion about drainage material being the cause for fecal fistulae, and too much drainage undoubtedly is a cause. We have had a rather high percentage of fistulae, 7 in 94 drained cases, or 7.5 per cent. Everything that had a discharge of thick consistency and a fecal odor we have called a fecal fistula. In only one case was there anything which resembled pure feces.

Of these 7, one was undoubtedly due to drainage that was too much and too prolonged; this was a case of abscess. In the remaining 6 cases, the fistulae appeared the day after operation in one case, in 2 cases on the second day, and in the other 3, the fistulae appeared

on the third, fourth and sixth days respectively. It seems probable that the fistulae which appeared on the first, second, third and fourth days, 5 cases in all, were due to the disease and not to the drainage. Every one of the 7 cases healed without secondary operation. In 3 of the cases the fistula persisted for three weeks, and in the other 4 the discharge persisted for four, seven, eight and thirteen days respectively.

POSTOPERATIVE CARE

The treatment that is so well-known is given to the complicated cases. This treatment requires detailed care. In the peritonitis cases, the glass tube is aspirated every twelve hours. Particular attention is given to the enteroclysis to see that there is no sagging of the line between the receptacle and the rectum. Morphine is pushed until the respirations approach the rate of twelve per minute. Water in teaspoonful doses is usually started in thirty-six hours. In the convalescent stage, too much eating is cautioned against, because it sometimes causes an exaggerated peristalsis and a kinking of the intestines.

CONCLUSIONS

Brilliancy in operating is not the prime requisite of the treatment of acute appendicitis and its complications. It was to this disease that Warbasse applied the aphorism that "*un bon operateur serait quelquefois un mauvais chirurgien.*" To plan what to do, or rather to know what to plan is essential. The lesson cannot be better emphasized than by the statement of Dr. Ashhurst from the essay, *The Surgeon and the Operator*, a lesson in strategy and tactics, that "no amount of excellence in tactics will repair a fault in strategy." [For references see author's reprints.]

EXTRA-ARTICULAR ARTHRODESIS OF THE HIP

BY BONE GRAFT, FOR TUBERCULOSIS OF THE HIP*

FRED H. ALBEE, M.D., SC.D.

NEW YORK

IN THE treatment of tuberculous joints, the fear of spreading the infection and of exposing the diseased tissues to secondary infection prompted surgeons, in the past, to leave the lesion untouched and unexposed and to institute such measures as would ensure immobilization and rest. If, however, the tuberculous tissue can be largely removed, and the bony elements can be coapted over a broad surface, the progressive surgeon no longer hesitates to carry out erosion. In certain joints, notably the knee, radical erosion is carried out because coaptation of the bony elements can be secured and ankylosis brought about. In the spine, the anatomical difficulties of resection in such an inoperable location and the danger of involving the spinal cord in either primary or secondary infection have always argued for conservative methods. In the hip, although resection and intra-articular arthrodesis have produced varying results in the past, such procedures are not well suited to the structure of the joint and the nature of the disease. Since excision of the diseased tissue in the head and acetabulum reduces the size of the one and increases that of the other, the procedure produces a dead space which there are no means of filling. Moreover, the impingement of the great trochanter on the soft parts overlying the rim of the acetabulum prevents telescoping and renders coaptation of the two elements of the joint impossible.

It was a consideration of these facts that led me, in 1910, to attempt immobilization of the spine by surgical measures that neither exposed the tuberculous area nor disturbed the lesion, and, in 1915, to undertake immobilization of the hip by similar means. In 1919, I reported a

method of performing extra-articular arthrodesis of the hip by means of grafts, taken from various autogenous sources, mortised into the bony elements outside the joint.

I recently reported a series of 31 such cases in which the clinical and functional results were satisfactory. A few months after operation the roentgen-rays in all cases showed the grafts firmly in place. Roentgenograms taken several years later revealed marked proliferation of the grafts and showed how firm was the bridging support given to the joint by this method. The average period of observation was six and a half years.

The operation is indicated: (1) when there is constant relapse of the adduction deformity in spite of long periods of conservative treatment; (2) if the adduction deformity recurs following Gant's osteotomy; (3) if the roentgen-ray reveals marked destruction of the head of the acetabulum or both; (4) if there are symptoms of active tuberculosis in adults or older children, even if the destruction of bone is moderate. It is also applicable in certain cases of osteoarthritis.

When destruction of bone has been extensive and spontaneous arthrodesis is prevented by the accumulated caseous material and by the impossibility of spontaneous coaptation of eroded head and acetabulum, as already stated, extra-articular arthrodesis is necessitated, particularly in older children and adults, by the continued deformity, pain and disability. On the day of this writing, I have performed this operation in the case of a woman who has been suffering with tuberculosis of the hip for thirty years. Twenty years ago the attempt to produce ankylosis by an intra-articular operation failed.

* Read before the Section on Orthopedic Surgery, New York Academy of Medicine, Jan. 18, 1929.

In this case, mutual recession of the two elements of the joint was responsible for the unusually persistent unfavorable condition.

This case also illustrates another strong argument for biological splinting at the joint itself as opposed to the usual mechanical devices. Long-continued bracing results in marked genu valgum or marked laxity of the knee joint with serious loss of function. In this case both these conditions were present, as the result of the action on the knee of two opposing forces; the one, the constant spasm of the adductors and tendency to adduction of the limb; the other, the action of the well-designed brace which opposes the adduction by its pressure on the lower leg. The internal lateral ligament of the knee gives under the prolonged strain and genu valgum results.

The particular method of bringing about arthrodesis depends on the relation of the trochanter to the ilium. When only moderate destruction of bone has occurred, the trochanter is relatively distant; as destruction increases, the trochanter lies more mesially, and may eventually come to impinge on the rim or on the ilium. In the first type of case, bridging with engrafted bone is necessary; in the second, the trochanter may be fixed by a sliding graft from the ilium or may be directly mortised into the ilium. In the first type the grafts for the bridge cannot be obtained in sufficient length and strength from the immediate locality and are taken from the femur or, better, from the tibia. I shall first consider the tibial grafts.

Because of the thinness and elasticity of the bone comprising the outer table of the ilium, a mortise suitable to receive the grafts can be satisfactorily made with a half inch chisel driven through the outer table of the ilium obliquely upwards between it and the inner iliac table with the handle of the chisel in close proximity to the trochanter. With the cutting end of the chisel still in the mortise prepared by it, located 1 inch posterior to the

anterior-superior spine, and 1 inch below the crest of the ilium, the handle is depressed onto the lateral surface of the trochanter at its anterior border, and used as a guide for some cutting tool, such as the scalpel, to mark on the periosteal structures the line where the motor saw is later to prepare a gutter for graft No. 1.

The same preparation is made for graft No. 2, except that the mortise in the ilium made about $1\frac{1}{2}$ to 2 inches posteriorly to the first one, and the scalpel mark is made on the posterolateral surface of the great trochanter.

Saw cuts are now made $\frac{1}{2}$ inch in depth with the motor saw, following the scalpel marks just made on the trochanter. With an osteotome driven into these saw cuts, fragments of the trochanter are displaced with the periosteal soft parts as hinges anteriorly from the saw cut for graft No. 1 and posteriorly from the saw cut for graft No. 2, so as to produce gutters to receive the two grafts.

The antero-internal surface of the tibia is then laid bare from the tuberosity of the tibia downward. With the motor twin saw set with the blades at approximately $\frac{5}{8}$ inch apart, a graft is removed by saw cuts made downward from the tuberosity of the tibia about 9 inches. With a motor saw this strip of bone is then cut into two segments. The upper ends of the grafts are cut in an oblique way like the end of a chisel.

The upper end of graft No. 1 is inserted into the mortise of the ilium with its lower end lying in the anterior gutter prepared in the trochanter. The oblique surface at the upper end is outward. With the author's bone drift or set (of which the carpenter's nail set is the prototype) placed on the trochanteric end of the graft, the graft is now driven into the iliac mortise. In this manner its trochanteric end is made to slide along the trochanter gutter and its proximal end to penetrate the mortise of the ilium by means of blows of the mallet upon the bone set.

Graft No. 2 is put in by precisely the

same technique. The firmer the grafts are driven into the iliac mortise, the closer do they hug the bottom of the trochanteric

FIG. 1. Tuberculosis of hip before extra-articular arthrodesis.

gutter because of the obliquity of the cut end of the iliac end of the graft. This plan of operation automatically immobilizes the grafts at both ends in a most gratifying way and no immobilizing bone ligatures are necessary.

The soft parts with fragments of the trochanter are drawn over the ends of the graft by means of interrupted strands of medium kangaroo tendon. The gluteal muscles are carefully drawn about the grafts by means of chromic catgut sutures.

The skin is closed with continuous suture of o plain catgut. Suture holes and the edges of the wound are puddled with 3½ per cent tincture of iodine.¹ The results are illustrated (Figs. 1 and 2).

If the graft is taken from the femur, the original incision is extended downward to expose the anterolateral aspect of the femur for 5 inches from the tip of the trochanter. By means of the motor saw and osteotome, a graft is taken from the femur extending from the tip of the trochanter to the inferior limit of the exposure, and including one-fifth of the diameter of the shaft. A pedicle of muscle is left attached at the upper end, and upon this as a hinge the graft is swung anteriorly

and then upward until the free end impinges on the ilium. A suitable site for placement of the graft is now determined, and a flap is raised in the outer table of the ilium to accommodate it. The graft is now pushed backward under the flap.

In neither case are any immobilizing bone ligatures necessary, if the grafts are accurately fitted, so that no foreign material is present to prejudice the "taking" of the graft.

When destruction of bone by the tuberculosis has been extensive, the trochanter may lie so close to the ileum (a half inch or less) that a sliding graft from the outer table of the ileum into the trochanter may be expected to provide adequate fixation of the joint. This procedure is more rapid than the two methods I have just described, largely because the ilium has been exposed in the Smith-Peterson-Sprengel method of approaching the joint and no extra incision is necessary.

In extreme cases, when the trochanter rests against the ilium, direct mortising of the two bones may be undertaken. The trochanter is first denuded of all soft tissue and periosteum both laterally and mesially. A gutter is made for it in the ilium by elevating a portion of the outer table just above the rim of the acetabulum. Abduction of the limb elevates the trochanter into the gutter. It may be necessary to reinforce with a graft obtained higher up on the acetabulum.

Such extreme cases are rare: I have only encountered two. The procedure is not ideal, since the operation is partly intra-articular, and should only be applied in those cases in which the tuberculous tissue has entirely disappeared.

I have thus offered a choice of two operations in each type of case. Which operation is performed depends on the pathological state of the joint and on the surgeon's preference. My own preference, when grafts have to be supplied from elsewhere, is for the tibial graft. It is naturally stronger than one from the upper end of the femur since its cortex is thicker. Since the portion of the tibia from which it is

¹ This operation is illustrated on page 217 of the author's textbook, *Orthopedic and Reconstruction Surgery*, Phila., Saunders, 1919.

taken is subcutaneous, the graft can be more readily and quickly removed, and with much less trauma and shock; the upper end of the femur is buried in thick masses of muscle the deeper of which are firmly attached to the bone. The shock attending an incision through muscular tissue of such depth and extending for 10 or 12 inches distally from the iliac crest is a serious argument against this method. Cannon has drawn attention to the gravity of such procedures. The removal of a section from this part of the bone is not an easy procedure. Moreover, it is desirable to spare the infected joint as much indirect trauma as possible. Since the viability of the graft will depend on the establishment of its circulation in its new position, it is desirable to minimize the disorganization of the circulation of its host and to choose some distant site for the source of the graft. When the graft is taken from the trochanter and swung upwards, the arrangement of the muscles attached to it is disorganized and the muscles themselves partly destroyed. For this reason the possibility of future arthroplasty is seriously jeopardized.

More important, perhaps, than all these reasons for my preference, is the fact that from the tibia sufficient bone can be taken for two grafts. The strength of two grafts supplied to different aspects of the arthrodesis is much more than twice that of one graft, on account of the application of the principle of truss work in structural mechanics. The validity of this argument was illustrated recently in a case in which a good result had apparently been attained with the femoral graft. On being interviewed in the course of the follow-up, the patient stated that she had been confined to bed on account of an attack of severe pain at the site of the operation. After a few weeks' absolute rest, the pain had disappeared. The x-ray now showed that the femoral graft (although as large as was consistent with the safety of the remaining portion of the femur) had broken and reunited during rest in bed. This happy and extraordinary ending does not discount

the danger of furnishing too little support for an arthrodesis which must withstand great strain if it is to function usefully.

FIG. 2. Same case showing grafts firmly in place. Only one graft shows because both are in same line with roentgen ray.

It is to be noted here that the symptoms were absent until the graft gave way, and disappeared again when the graft united. The use of two tibial grafts has never been followed by fracture in my cases.

The method which I have described for using the femoral graft is a modification of the Hass or Hibbs method. As originally carried out, this method did not appear to be extra-articular, and I varied it so as to keep away from the infected zone. I have described this modification here, with such comment on the operation in general as my experience with it dictates. Whichever of the four methods the surgeon chooses, he will do well to be guided by the desire to avoid infected tissue when possible, and he will naturally prefer the simplest technic and one least likely to be associated with trauma and shock. He

should bear in mind the possibility of future arthroplasty, since arthrodesis may be only half way to the surgical ideal. The difficulty attending such future operation depends considerably on how the arthrodesis was affected. I have had one case for arthroplasty four years after arthrodesis. The tibial grafts had been used for fixation.

The success of these methods depends largely on accuracy of fit of the graft. By means of such accurate tools as the adjustable twin motor saw, the precision of a joiner can be emulated; the dimensions of the graft and its gutter are made to correspond accurately. The graft, when hammered into place and covered with the original soft tissues, will remain in place and the bones will remain in their fixed position if a cast is properly applied. Since the ultimate solidity of the graft is the result of a biological process, nothing should be done to hinder osteogenesis or to weaken the graft. Hence the necessity for avoiding immobilization with non-absorbable foreign material such as wire, screws and boiled-bone pegs, which always have a destructive effect on the host bone. This is of particular importance since osteogenetic power in tuberculous patients may be very low, and should always be considered low when the operation is planned.

The surgeon can no longer get along with an accurate knowledge of anatomy and some dexterity with knife and needle. The general surgeon must have a clear idea of the functions of the parts he is manipulating and of the forces of destruction which he is fighting as well as the forces of repair which he is encouraging. In addition, the orthopedic surgeon must have a keen mechanical sense, a reasonable acquaintance with the laws of mechanics and some experience in the use of tools. One must frankly say that the operating room is not the place, in all fairness, to begin one's acquaintance with saws, chisels and mallets; and a surgeon must be very confident in his inherent mechanical skill if he undertakes delicate work in bone

grafting without ever having done precise mortising in hardwood. It was to assist the precision of bone surgery that I had recourse to such exact instruments as the twin motor-saw and the dowel-shaper. There are surgeons who insist that absolute accuracy can be attained with the osteotome, and others who believe that absolute accuracy is unnecessary. The first might find illumination in a visit to the carpenter's bench; the second, I believe, will not find their contention in harmony with the physiological and biological principles that underlie the union of engrafted bone.

DISCUSSION

DR. LEO MAYER: In dealing with children the problems that we find most difficult are: When is an operation indicated? What is the most favorable time? Are you to do an arthrodesis in every case where you are sure tuberculosis is present? Are there certain cases in which there is a chance that cure may occur with function of the joint? And if you do decide that operation is necessary, what is the bet?

Although, in my opinion, arthrodesis is the operation of choice, I would like to urge the bifurcation operation as an alternative procedure in cases of quiescent tuberculosis when there has been extensive destruction of the head. The advantage of the operation is the retention of motion and, at the same time, the production of a stable joint in which the weight of the body pulls on the uninfected femoral shaft. In the two patients upon whom I did this operation, the result has been admirable.

The important question is how soon should the operation be performed and what kind, and which is the most preferable method of approach?

In children suffering from a tuberculous hip, if an immobilizing operation is to be done, which is to act only as a temporary stabilizer would it not be better to insert here an heterogenous graft which would absorb eventually of its own accord, instead of an autogenous graft which requires greater mutilation and a later operation for its removal? Another question is: How long shall the adolescent type be treated conservatively before proceeding to do the extra-articular grafting operation?

DR. KRIDA: I think that most of us are very glad to secure ankylosis in these cases without entertaining the possibility of doing an arthroplasty later. It seems to me that one

very important consideration enters into this: that if we are to be led into doing arthroplasty, after an operation to secure ankylosis, there ought to be a definitely established diagnosis of tuberculosis; we know that some of these joints look in the roentgen x-ray pictures like tuberculosis and they act like tuberculosis, but on section no tuberculosis is found. The argument for arthroplasty will have more weight if a diagnosis of tuberculosis is more definitely established at the time of operation.

DR. WEIGEL: I think we are all agreed that when possible it is best in advanced cases to place our graft in an extra-articular manner as Dr. Albee has described. However, I recently operated upon a case in which there proved to be more destruction than I expected. I had scarce y gone through the skin before I opened into a large abscess which connected directly with the capsule so that any operative procedure would of necessity have been intra-articular rather than extra-articular. Because of the closeness of the great trochanter to the ilium I placed two large grafts taken from the ilium between the great trochanter and the side of the pelvis and closed the wound as usual. It is now almost two months since this patient was operated upon and she is still in plaster, but the wound has remained entirely healed.

DR. ALBEE, *closing*: The question when should we operate children: I think we should select cases principally from the older children and adults. As for selection in the younger children, it is a matter of minute study in cases of long continuance of the tuberculous process. If we have a pathology with a large amount of destruction with recession of the articular surfaces and are certain we are not going to get function and a movable joint, and judge from the pathology that a spontaneous arthrodesis will be long delayed, I think we should do an extra-articular arthrodesis; but if we have any reason to believe we can get a functional result in the child or will get a reasonably early arthrodesis in unfavorable cases without operation, we should not operate. I do not feel as strongly as some of our confreres about operating on all of these cases. I believe we should operate on a large percentage.

Now as to the bifurcation operation, it does not appeal to me very much. I cannot understand the rationale. Here we have a case of active tubercular lesion, with an immense amount of caseous material, and it is undis-

puted that we want immobilization to get healing. If one has a case in which the tuberculosis has healed, and we are sure of it, and there is adduction and we want to increase motion, we might do it instead of an arthroplasty; but in such cases as we are discussing here I do not quite see the rationale of its use.

How long shall we wait in adolescent cases? I believe that in adults we should wait a shorter length of time. It needs less argument to justify an operation on an adolescent than on a child of five or six, and I should put the adolescent in the same category as the adult.

Concerning arthroplasty: I have always championed arthrodesis in such cases but I believe that in a few selected cases one may resort to arthroplasty, providing the time elapsed after the last symptom is sufficiently long and a thorough roentgen-ray examination shows ideal healing at the joint with homogeneous bone structure. I believe the hazard is not too great. Shall we do it? A stiff hip in good posture will give good function. In this family, they wanted it, and they are delighted with it; but I would not have pressed them.

Some one asked about the position of the limb following arthrodesis. That depends on how much shortening exists. The desire is to make up for the shortening in a practical way by putting the limb in a position of sufficient abduction with pelvis. We put it in 10 or 15 degrees of flexion.

I would not consider the grafts Dr. Weigel described as wholly intra-articular. To be sure they did go through the tuberculous area, but they were generously mortised into healthy vascular bone on either side. I have put in a number of grafts through tuberculous areas. In my first book¹ I described an extra-articular arthrodesis of the ankle, which was almost completely disintegrated, and in that case I put in three grafts: one mortised into the internal malleolus and down into the os calcis, one into the same malleolus running forward into the internal cuneiform bone; and the third into the external malleolus down to the cuboid; they grew in and the man had a functional foot, ankylosed stiff, but it overcame the pain and the tuberculosis. All three grafts were well mortised and well contacted with healthy bone on each side of the tuberculous area. I have had similar experiences in the spine where the abscess had penetrated through between the spinous processes.

A CUTICULAR SUTURE*

MICHELE TOMAIUOLI, M.D.

NEW YORK CITY

THE purpose of this cuticular stitch is to cause as small a scar as possible. I have seen used all kinds of

The suture in question in its essential is the one prefixed by the word "mattress." However a marked degree of perfection

FIG. 1. Continuous alternating suture in appendectomy incision.

stitches with varying results as to scar formation, and I came to the conclusion that Halstead's subcuticular suture and Stewart's stitch were by far the best in bringing about a perfect coaptation of the skin edges. But the former cannot be used in drain cases, and the latter requires a great expenditure of time which is detrimental to the patient for undue prolongation of anesthesia adds materially to the postoperative shock.

Now it may or may not be so, but, certainly in the mind of the laity, a scar mirrors the ability of the surgeon in being a skillful operator. And then will not the laity wonder what sort of "butchering" was done "inside" of them if the "outside" shows such a ragged, angry-looking scar, especially when compared to the scar of a more fortunate neighbor?

FIG. 2.

FIG. 2. Continuous alternating suture in pelvic laparotomy.

FIG. 3. Suture in same patient as Figure 2 removed on eighth day following operation.

in its purpose is attained when applied to cuticular incisions with the aid of small pieces of rubber tubings utilized as shown in Figures 1 to 5.

These pieces of rubber tubings, $\frac{1}{4}$ in. long, can be easily obtained by cutting them from a Dakin tube. Their use, I believe, is original.

The advantages of such a suture become at once manifested when viewing the accompanying photographs and sketches. It can be used as an interrupted or as a continuous suture with the same identical results. And trained hands can make speed with it.

It is of especial advantage wherever the scar may show, and in the flabby, pendulous abdomen of multiparae where, according to my experience, there is an

* Submitted for publication August 13, 1929.

infallible tendency for the skin edges to overlap when sutured.

The suture in question makes overlapping impossible by the use of the small pieces of rubber tubings whose purpose is twofold: first, to prevent the silk from cutting through the skin, and second to maintain the skin edges everted, thereby assuring a perfect alignment of the cut surfaces.

I want to add that better results will be obtained if the needle be inserted slightly obliquely from without in, and then from within out. This gives the superficial layers of the corium a tendency to remain throughout the healing process in perfect opposition.

CONCLUSIONS

1. The author confesses his failure to see in practice anything similar to this, nor in the literature a prior description of the same technic.

2. He believes that a happy medium

has been struck in this suture, in that (a) the result is better and certain; (b) it can be used both as an interrupted and

FIG. 4. Schematic drawing of alternating continuous suture.

FIG. 5. Schematic drawing of interrupted suture.

continuous suture in drain cases and clean ones with the same identical result, and (c) it can be used without undue expenditure of time.

TREATMENT OF ACUTE HEAD INJURIES*

A FEW CONSIDERATIONS

CARL W. RAND, M.D.

LOS ANGELES, CALIF.

IT IS assumed that the patient is unconscious and has sustained a cerebral concussion, contusion or intracranial hemorrhage. Move as carefully as possible. Elevate the head of the bed, unless the patient is in shock. Place ice-bags to the head, using several to pack the head and give the full benefit of the ice. If the patient does not tolerate ice do not try to force it on him. Quiet is better without ice, than constant resisting with it. Saline cathartic by mouth or rectum may be used. Use morphine as little as possible. Never employ $\frac{1}{4}$ grain doses and do not leave a "p.r.n." order for the drug. Morphine in large doses is contraindicated for three reasons: (1) it contracts the pupils, covering up inequalities of the pupils which may be present; (2) it tends to mask the symptoms of oncoming stupor which may be due to cerebral edema or hemorrhage; (3) it often fails to quiet the patient, although it depresses the respiration and pulse. If morphine is used small doses are suggested.

A bleeding ear is best treated by placing sterile cotton in the external auditory canal. Cleansing the ear by irrigation of various sorts is contraindicated.

All scalp wounds should be carefully inspected before suture, to make sure whether or not a skull fracture in the vicinity is present.

When cerebrospinal rhinorrhea is present the patient is kept very quiet in bed and told to keep from sneezing, coughing or straining. Traumatic pneumocephalus may occur at times and require removal of air and repair of the torn dura.

Lumbar puncture is recommended for diagnostic purposes in selected cases. It is important to know the character of spinal fluid when considering the possibil-

ity of intracranial hemorrhage. Promiscuous lumbar puncture may be dangerous due to the possibility of medullary herniation in the foramen magnum.

The use of hypertonic glucose (50 per cent), is almost a routine procedure in these cases.

In correcting depressed skull fracture, save the fragments whenever possible.

DISCUSSION

DR. ALDEN: I do not know of any class of injuries that is so poorly managed by the average physician as acute head injuries.

A few years ago, Sharpe of New York found that the mortality in skull fractures was 50 per cent; that was also true elsewhere. A year or two ago Dr. Rand studied over 180 skull fractures at the Los Angeles General Hospital. He found that formerly the mortality was 50 per cent, the same as Sharpe's, but since special attention has been given the cases the mortality has dropped to 27 per cent. In other words, the treatment of skull fractures by specialists has markedly reduced the mortality. The more we hear from these specialists the better will be the treatment of this class of injury.

One of the things Dr. Rand mentioned was the danger of sewing up a scalp wound with a depressed fracture beneath. If a scalp wound is not large enough to determine the condition of the skull, I make it larger. The size of a scalp wound is of no importance compared with the danger of overlooking a depressed fracture. I think this is very important.

Dr. Rand spoke of the use of saline cathartic. Epsom salts is the best drug that is always available, that you can use in head injuries. Give it by mouth if you can, by rectum if you must, or by vein if you have it in ampules. You can always get Epsom salts. Every country grocery store has it. It reminds me of the automobilist who ran out of oil while touring in the country. He drove up to a farm house and asked if they had any oil. They replied: "No, but we have some Epsom salts."

SPINAL ANESTHESIA

LIGHT SPECIFIC GRAVITY ANESTHETIC SOLUTIONS VERSUS HEAVY FURTHER OBSERVATIONS*

FLOYD T. ROMBERGER, M.D.

LAFAYETTE, IND.

IN THE induction of spinal analgesia by subarachnoid block, there are, in general, three principle types of anesthetic solutions used: first, those in which the specific gravity and isotonic properties of the solution are identical, or almost so, with spinal fluid; secondly, those which are lighter in specific gravity than is spinal fluid; and, thirdly, those which are heavier in specific gravity than is spinal fluid. This has been true since almost the very earliest use of spinal anesthesia and continues so today. In a previous manuscript,⁶ the writer discussed somewhat at length a number of rather intimate experiences and deductions resulting from an extensive use and an intensive study of Dr. Pitkin's novocaine solution, called spinocain,⁵ which is lighter in specific gravity than is spinal fluid. After the lapse of time and the vicissitudes of trial and error, spinocaine having ably demonstrated its controllability and availability in spinal anesthesia, it became apparent that a still greater measure of usefulness and adaptability would be inherent to spinal anesthesia if a solution which was heavier in specific gravity than is spinal fluid also were at hand. Accordingly, there has been developed a solution, for the present called novocaine solution heavy, which differs from regular spinocain in that instead of being a 10 per cent solution of novocaine and being lighter in specific gravity (spinocain), this solution, novocaine solution heavy, is a 40 per cent novocaine solution and is heavier in specific gravity than is spinal fluid. At the same time, novocaine solution heavy maintains the same properties of viscosity and retarded diffusibility as does spinocain. While this relatively new product is as yet not on the market for general distribution, the

writer has been complimented by being favored with a supply of a sufficient quantity for the purpose of making clinical tests and observations; and it is from a close study of his records and the results obtained in using novocaine solution heavy that he wishes herewith to present a few opinions.

The first thing to remember, in considering the employment in spinal anesthesia of these two solutions, is their *difference in specific gravity*. With the *light solution*, the patient's head must be *kept down* in order to avoid blocking the cervical nerve roots and the medulla; with the *heavy solution*, the head must be *kept up* to obtain the same result; i.e. *for spinocain, Trendelenburg position must be favored*; whereas, *with novocaine solution heavy, Fowler's position must be used*. Not only are these points of essential and fundamental interest in the life and welfare of the patient, but they are of practical importance in adapting your anesthesia to suit the needs of the surgery at hand.

Supposing abdominal surgery of a pelvic nature is about to be performed. Naturally, it is easier for the surgeon to work out the pathological problem if the patient is in the Trendelenburg position; because, then, the abdominal contents tend to gravitate out of the way of the surgeon, and a lesser number of packs (or none) need to be used. On the other hand, suppose gastric or gall-bladder surgery is anticipated. In this instance, slight Fowler's position often is an advantage; for, then, the abdominal viscera again fall away from the field of operation. This is a very remarkable and almost marvelous feature in spinal anesthesia; to the uninitiated and uninformed, it is almost unbelievable. Still further, experience and observation

* Submitted for publication July 8, 1929.

show that a great many patients suffer more or less respiratory embarrassment when placed in the Trendelenburg position; especially is this true of cardiacs, asthmatics, and elderly people in general. For these cases, a slight Fowler's position is much more comfortable and more favorable than is the Trendelenburg. Aside from these factors, there are any number of cases which can be operated in either position to an advantage, as far as the operation itself is concerned, and the problem merely becomes one for the anesthetist to determine just how high he wishes to produce motor or sensory block. It must be apparent, therefore, that once you have perfected your technic in the use of these two solutions of different specific gravity, your ability to harmonize the anesthetic procedures with the surgical problem at hand is markedly enhanced. Greater flexibility of choice is yours.

Now, keep in mind certain anatomical features which inevitably must have a bearing on the selection of the heavy or light solution. First, the anterior nerve roots of the spinal nerves control voluntary motion and the superficial and deep reflexes;² hence, when they are affected by your novocaine solution, you have muscular paralysis and muscular relaxation, *motor block*. Secondly, the posterior roots of the spinal nerves are sensory;² they control pain, tactile, temperature, and muscle sense; accordingly, when these are affected by your novocaine solution to a sufficient degree, all sensations of pain, touch, and temperature are lost, *sensory block*.

Accordingly, to visualize what is about to occur when these solutions of different specific gravity are injected into the spinal canal, perform a little experiment as shown in Figure 1.

Take an ordinary test tube, fill it half and half with two solutions of different specific gravity, such as water and ether, stopping the tube at the top. Now imagine this test tube as representing the human spinal canal,

with the stopper being at the head. Hold the test tube vertical in such a position as shown in Figure 1, A. Your water, being heavier than ether, is at the bottom; the ether, being lighter than the water, is at the top. Now, hold the test tube in 15° Trendelenburg position, as shown at B. The ether, being lighter in specific gravity, rises toward the opposite end of the tube from the head (cork or stopper). This is what results when regular spinocain is injected into the spinal canal, ether representing the lighter specific gravity anesthetic solution, water the spinal fluid. Now, hold the test tube in position C, 15° Fowler's position. Here an opposite effect is obtained. The water, being heavier than the ether, gravitates toward the bottom of the tube. The water now represents a heavy anesthetic solution; the ether, in this case, represents spinal fluid.

Let us imagine that these two test tubes are lying on an operating table, placed respectively in Trendelenburg and Fowler's positions. It must at once be clear to you that, with light solution and position B, the anterior nerve roots will be affected higher up along the cord than are the posterior roots; vice versa, with heavy solution and position C, the posterior nerve roots will be affected higher up on the cord than are the anterior roots. In other words: with spinocain, motor block (paralysis and muscular relaxation) extends higher on the body than does sensory block; with novocaine solution heavy, sensory block extends higher than does motor block.

It is of extreme importance for you to be able to visualize these factors, as they have a bearing of great moment in the conduct of your anesthesia and its adaptation to the patient and surgery at hand.

Now let us transpose the findings with the test tube in Figure 1 to the human spine, as pictured in Figure 2. At A, the light solution, spinocain, is represented within the spinal canal. At B, novocaine solution heavy is shown within the spinal canal. By comparison, we find at A the sensory roots are paralyzed as high as the second dorsal vertebra while the motor roots are paralyzed two or three sections

higher, the sixth cervical. On the other hand, at B, with novocaine solution heavy, we observe that the sensory roots are

fixed in your mind, it must be apparent that when using spinocain, the light solution, motor paralysis occurs several seg-

FIG. 1.

paralyzed to the seventh cervical vertebra, while the motor roots are paralyzed only to the third dorsal vertebra.

In the illustration of these two spines, A showing light anesthetic solution and B showing heavy anesthetic solution, is exemplified the highest level of spinal anesthesia which is warranted for any type of surgery, if you are at all interested in the welfare of your patient; and, most emphatically, this height should not be attempted by amateurs. Experience first must be gained in lower types of anesthesia and surgery. However, it can readily be determined that the diaphragm, receiving its motor nerve supply from the third, fourth, and fifth cervical segments of the cord, is not paralyzed, even though sensory anesthesia extends above the nipple line. The abdominal muscles and accessory respiratory muscles indeed are blocked, but observation of the epigastrium will show movement there transmitted to it by the diaphragm. With the lower levels of anesthesia, comparing the two solutions of different gravity, the same relative difference in the sensory and the motor block obtains.

With Figures 1 and 2 thoroughly

ments of the cord higher than does sensory paralysis; and, when novocaine solution heavy is used, sensory paralysis extends several segments of the cord higher than does motor paralysis. Reasoning further, with the light solution, maximum loss of muscle movement and resultant relaxation occurs at the expense of a somewhat lessened extension of loss of pain sense; whereas, when novocaine solution heavy is used, loss of pain sense extends higher than does loss of muscle tone and relaxation. These factors are of extreme importance for you in determining which solution to use in adapting your anesthesia to any particular type of surgery, and there is no place in the recent literature on spinal anesthesia where this feature previously has been pointed out. It helps you to determine, by understanding these factors, how high you should ascend with your block (sensory or motor) to produce any desired or required result. It permits the spinal anesthetist to conform and attune the anesthesia in proper proportions to meet any surgical dilemma.

Still further, the illustrations explain to you the point previously mentioned as to why cardiac, asthmatic, and elderly

people in general do somewhat better under spinal anesthesia induced with the novocaine solution heavy than they also diffusion, i.e. the amount of spinal fluid used to expand the original solution which tends to render it more nearly

FIG. 2.

do when the light solution is used. Translating the findings to the anatomy involved, you find that while sensory block may extend as high as the clavicles, motor block may not involve even the loss of all of the intercostal respiratory muscles. Of course, the extension of your block will vary a great deal, also, depending on the dosage of novocaine used and the amount of expansion with spinal fluid, as your previous experiences with spinocain will have taught you; yet, if your observation parallels mine, it will be almost immediately apparent to you that the excursion of the diaphragm and accessory respiratory muscles is much more free when novocaine solution heavy is used in spinal block, even for abdominal surgery, than when the light solution, spinocain, is used. It must be borne in mind that the illustrations are diagrammatic; the factor of capillarity enters into the problem,

the same in specific gravity and isotonic properties.

With different classes of patients, some of which just have been mentioned, one must be extremely careful not to embarrass their respiratory apparatus even to the slightest degree; and, for this reason, novocaine solution heavy produces such happy results that one cannot always agree with Labat⁴ and others who claim that to use an anesthetic solution in spinal block which precludes the use of the Trendelenburg position, is to invite disaster. Rather, experience has proved quite conclusively that a slight Fowler's position, even at times as much as 15°, *produced under properly supervised expert technic and close observation*, may be employed to very great advantage.

If ephedrine is used in proper amounts, as pointed out in a previous manuscript on this subject,⁶ these patients do not have

pallor, sweats or cyanosis. Their blood pressure, pulse and color run along very normally. In fact, it is quite easy to make them appear much pinker in the lips and to increase their blood pressure above normal. Experience has proved ephedrine so superior to adrenalin in spinal anesthesia that there is no comparison. There are those that claim that ephedrine is without effect;³ surely they are not giving enough; they are over-cautious as to dosage. To piddle along with a dose of 50 mg. is indeed trifling; routinely administer 100 mg. and do not hesitate to use 150 mg. if indicated. These doses are well within the minimum limits of toxicity and produce no discomfort or disagreeable sequelae. The maximum safe dose of ephedrine is given by Solis-Cohen as 5 gm. or 5000 mg.⁵ For every authority which can be quoted saying that ephedrine is without effect, it is possible to quote an equally weighty authority who claims and proves that adrenalin is entirely without benefit in spinal anesthesia unless given intravenously, and, even then, the effect lasting only a few minutes. Be that controversy as it may, this most certainly is true: To get any response whatsoever from ephedrine or adrenalin, the calculated dose of drug must be given before the block is established,⁵ i.e. before splanchnic paralysis has occurred; otherwise you court disaster. With proper technic in the use of ephedrine in spinal anesthesia, the so called "dry wounds" (i.e. low blood pressure) are not seen; the arteries and arterioles spurt vigorously; some surgeons say more vigorously than with ether, certainly more than with gas-oxygen.

Naturally, of course, coming back once again to a discussion of the position of the table, after twenty or thirty minutes have elapsed and the anesthesia has become fixed, should occasion arise, Fowler's position may be lessened even to the point of making the table level, if it will add to the patient's comfort or to the convenience of the surgeon. This latter fact also applies to the use of

spinocain (light) after the solution becomes fixed, certainly after thirty minutes or more; then, the degree of Trendelenburg position may be lessened until the patient is almost or entirely level without fear of extension of the block.

Aside from all the aforementioned factors, there are many instances favorable to the use of novocaine solution heavy. For example, by no other means in spinal anesthesia, i.e. intradural block, can the effect of your anesthetic agent be limited strictly to the perineum, the so-called saddle anesthesia; and, further, there is no other method by which the relative height of sensory anesthesia and motor paralysis (relaxation) can be regulated with such a degree of nicety and accuracy as by a thorough understanding and a proper technic in administering solutions of light and heavy specific gravity. It gives the spinal anesthetist an almost unlimited number of variations by which he can adapt the anesthesia to the needs of the patient and the requirements of the surgery at hand.

Novocaine solution heavy also is susceptible of very fine regulation as to your constant percentage factor, something discussed in a previous manuscript. Spinocain (light) as now on the market, is a 10 per cent solution of novocaine; in other words, one 2 c.c. ampoule contains 200 mg., and two such ampoules, totaling 4 c.c. of spinocain, contain 400 mg. of novocaine. Four cubic centimeters of spinocain expanded to a total of 8 c.c. (and this should be your maximum dose for a first injection under any circumstances) gives you the constant percentage factor of 5. Novocaine solution heavy, as used for clinical study, is a 40 per cent solution of novocaine, and at present is put up in 0.5 c.c. ampoules. One-half cubic centimeter, therefore, contains 200 mg. of novocaine, and 1 c.c. full contains 400 mg. Referring now again to Figure 1 (or Figure 2), it must be apparent to you that a lesser amount of spinal fluid (or total of expansion) must be used to obtain equivalent sensory block when

using the heavy solution than when using the light. Eight cubic centimeters total expansion of spinocain, whatever your constant factor may be, will be required to give you sensory anesthesia, by proper regulation of your Trendelenburg position, to a point somewhere between the nipples and clavicles, in average cases. Five cubic centimeters total expansion of the novocaine solution heavy will carry your sensory anesthesia to the clavicles, or even to the neck. Four cubic centimeters total expansion of the heavy solution, irrespective of whether 0.5 or a full cubic centimeter of novocaine solution heavy is used, has been my maximum expansion. For routine use, it is preferable to regulate the height of the sensory and motor block by variations in the degree of Fowler's position. What constant percentage factor to use for different surgery must be worked out by each individual spinal anesthetist, as his experience enlarges. Start with minimum doses and minimum expansion and gradually develop your strategy until you can finesse each case at will, i.e. use maximum dosages with minimum expansion or minimum amounts with maximum expansion. You soon will learn how to secure prolonged anesthesia (even up to three hours if needed) by variation of the percentage factor.

For emphasis, it is well to repeat: Where spinocain is used, maintain Trendelenburg position until your solution becomes fixed; where novocaine solution heavy is used, keep the patient in Fowler's position until the solution becomes fixed. If you cannot comprehend the simple facts contained in this one paragraph, then *stay away from spinal anesthesia, or someone will pay with their life through your lack of understanding of these basic and elemental fundamentals.*

With a constantly enlarging experience in spinal anesthesia, the writer is more and more firmly convinced that, to obtain uniformly optimum results in the block, uniform or corresponding percentages of novocaine must be injected into the sub-

arachnoid space. Given patients of equal size and weight and volume of spinal canal, a fixed coefficient or a constant percentage of novocaine produces anesthesia of a given degree and intensity (lasting ability). Increase your novocaine percentage by one-half (i.e. from 5 to 7.5) and you will double the length of anesthesia; double the percentage (i.e. 5 to 10) and the anesthesia will last four times as long. This can be demonstrated to anyone's complete satisfaction, with both the light and the heavy solutions. It is one of the main reasons for the superiority of the Pitkin technic; because, with it, large enough amounts of novocaine can be used to satisfactorily block the patient for even the most prolonged surgery. "It has been definitely proved that amyloprolamine and propantriol not only produce viscous solutions that prevent dissemination and mixing with the spinal fluid, but they also reduce the toxicity of novocaine, permitting three and four times as much to be used without harm."⁵ This factor is of extreme importance for the spinal anesthetist who is inducing subarachnoid block for the "other fellow." You do not know how long he may operate, a point stressed in a previous contribution.⁶ Strange as it may seem and simple as it appears, most surgeons are not familiar with, or do not care to use, field-block; consequently, if your spinal anesthesia does not last *long enough* and supplemental local or adjunctive gas-oxygen is needed, upon you will fall the odium of failure and thus cast reflection upon spinal anesthesia. Labat⁴ and Evans³ give the operating time available under spinal anesthesia, where 100 mg. to 120 mg. of novocaine are dissolved in spinal fluid, as from three-fourths to one and one-half hours, with an average of one hour. With spinocain or novocaine solution heavy, 400 mg. to 600 mg. of novocaine can be used when needed; and, as already reported⁶ there is a record of one patient where 1200 mg. was injected without toxic effect. Also, many records exist of cases

where the surgery lasted considerably over two hours without supplemental anesthesia. However, *do not attempt these dosages until you have perfected your technic and judgment by a study of your previous cases.*

In analyzing my personal records, it is found that in the first series of cases the light specific gravity solution was used in 76 per cent of the cases and the heavy solution in 24 per cent; in the second series, the light solution was employed in 48 per cent and the heavy in 52 per cent. This is due to the fact that one constantly learns a fuller and more complete expression of the benefits to be derived from the use of novocaine solution heavy. Naturally, it is the solution *par excellence* for all strictly rectal surgery, vaginal and perineal surgery, and surgery on the lower limbs. An hour of complete anesthesia can be obtained with the very minimum doses of novocaine (a very small percentage factor) and the anesthesia can be limited in its extent to a nicety almost beyond belief. Novocaine solution heavy also is preferable in all obstetric surgery and manipulations with the exception, possibly, of cesarian section. Hernias, especially in elderly individuals, and prostatectomies best are handled with the heavy solution. With perineal and cervical repair work, plus laparotomy for uterine suspension and appendectomy, use heavy solution with a high constant percentage factor; keep the patient in 15° Fowler's position for the repair work, then level the trunk but bend up the head and neck (from second dorsal vertebra) for the abdominal part. This will give anesthesia long enough and at the same time not interfere with the surgeon. For gall-bladder surgery, gastric surgery, and appendectomy, take your choice, remembering that with the light solution motor block is higher than sensory block and with the heavy solution vice versa. For hysterectomy and pelvic surgery, use the light solution with a high constant percentage factor and close observation of degree of Trendelenburg position.

This only too brief discussion of the possibilities inherent to the use of solutions of different specific gravity in spinal anesthesia gives you an idea of the almost *infinite adaptations* at your command. Many others will occur to you as you advance in knowledge and experience. *Study and analyze each succeeding case.* As in general anesthesia, well known to all, no two individuals react exactly alike to the anesthetic agent, even though the basic fundamentals remain the same, so too in spinal anesthesia. Perfection in technic alone is not sufficient; judgment must be used. Judgment is the sum of knowledge plus experience. Knowledge alone leaves something wanting; experience, without study and analysis to acquire knowledge, also will display a certain lack. The two, knowledge plus experience, must be added to formulate judgment.

In a previous discussion of spinal anesthesia the writer pointed out the advisability of boiling everything (needles, syringes, ampoules, etc.) as an adjunct to aseptic technic. The general surgeons usually are content when they can keep their incidence of infection in clean cases down to as low as 3 per cent (records from good hospitals), but let the spinal anesthesiologist approach a degree of even 0.1 to 0.2 per cent and he would have to leave the city. *It just dare not be done!* At present, two parallel series are being run; at one hospital, everything is boiled twenty minutes; at another, everything is autoclaved ten minutes at 250°F. and 15 lb. pressure. Both methods seem equally effective; the latter is a little less "messy."

In conclusion, the writer wishes to depart from the formality of the manuscript to state that in a period covering ten years of active general medical and surgical practice, plus an additional period of ten years of exclusive devotion to the art and specialty of anesthesia, he has found nothing in these two decades which has provided him with the mental stimulation and brain cell exhilaration which has resulted from the study of and experience in spinal anesthesia. [NOTE: For references see author's reprints.]

HYPERTONIC SALINE SOLUTIONS IN INFECTIONS*

KEMP P. NEAL, M.D.

RALEIGH, N. C.

SINCE the days of Lister many have been the bactericides used in combating sepsis. Many have been tried and discarded for newer ones. Each year brings a new one claiming special advantages over all previous ones.

There are many chemicals that are capable of killing bacteria in situ or test tube, but the great objection to most of them has been, and still is, that they also kill or destroy cellular tissue. Any agent which has enough potency to kill bacteria will very often kill the cells in and around which the bacteria are growing and giving off their toxins. There does not seem to be any question about the fact that many of the present day antiseptic agents definitely injure tissues. Personally I have noticed, since the advent of mercurochrome, that fresh lacerated wounds, potentially infected, heal by first intention more often by using this agent than when the time-honored tincture of iodine is used. Many of these agents tend to coagulate blood or lymph or protoplasm, forming an impenetrable membrane over the deeper tissues. Some are rendered practically inert by precipitation by the salt in blood and lymph.

Many of these objections have been met by a newly discovered agent, S. T. 37, introduced by Dr. Leonard. It is claimed that this agent has the special virtue of having a very high phenol coefficient, being non-injurious to tissue, and having a special faculty of penetrating deeply into tissue because of its low surface tension. I wonder just how deeply it will penetrate. It requires quite a play of the imagination to think of a substance finding its way through cell after cell or between cells, reaching the depths of tissue where the most serious part of

the infectious processes is taking place. Any infection which is near the surface or on the surface is rather easily reached and combated. It is the deep-seated ones that give us most concern. Here the organisms are many, many cells away from our antiseptic agent, often separated by an area of infiltration, edema and congestion which add to the difficulty of reaching them.

Remembering the principles of physiology and physics with reference to tissue fluids, blood, and lymph as demonstrated by osmosis, diffusion and dialysis, thought was directed toward these principles in an effort to find an agent which would help rid tissue of infected material. For a hasty review of these principles allow me to illustrate the physical laws of osmosis, diffusion and dialysis which play such an important part in the methods of combating infection to be discussed.

If a solution of salt, and water in which there is no salt, are separated by a membrane which is permeable to the molecules of salt and water, water molecules will flow through the interspaces of the membrane to the salt solution, thereby raising the level of the latter. This response to the difference in concentration of fluids separated by a membrane is osmosis, and the pressure exerted against the membrane is osmotic pressure. Now if white of egg and salt be in the solution placed on one side of a membrane, and plain water in the other, there will be a passage of salt molecules over to the water, but none of the egg. This process in which salts which are diffusible separate themselves from substances which cannot accompany them through a membrane is dialysis. Diffusion on the other hand is simply a mixing of molecules of two solutions or gases when

* Submitted for publication August 20, 1929.

brought into contact, i.e., the spreading or scattering of molecules through agreeable media.

When two solutions of saline of different strength are separated by a membrane, there will be a flow of water molecules from the weaker to the stronger solution until there is an equality of osmotic pressure on the two sides of the membrane, or as much salt on one side as the other. In nature these same laws are at work, the protoplasm of the cells representing the solutions and the cell walls representing the membranes. There are continuous differences of concentration in body fluids in different localities and under different circumstances, in carrying out nature's processes of metabolism. If one cell has a higher concentration than its neighbor there is a tendency for the weaker to give up some of its fluid to the stronger in an attempt to equalize the two.

It is unquestionably true that physico-chemical processes occurring in the protoplasm of the cell change the permeability at different times and under different conditions. It is equally true that these processes already described are only true for crystalline substances which are soluble in water, and do not hold true for colloids which are only slightly diffusible, if at all. Hemoglobin is an exception to this; it is crystalline and diffusible.

Suppose we surround living cells with a hypertonic solution of salt in situ, what will happen? There will be a flow of tissue fluid, serum and lymph, from the cells nearest the solution into it, in an attempt to reduce its strength to that of the cells themselves. The cells farther away from the solution will feel the effect of this change in osmotic pressure, and there will be an effort to stabilize the osmotic pressure of the tissues for a considerable distance away, the result being a passing of toxin-laden lymph and intercellular fluid into the solution. This process results in a milking of the tissues of their septic content, at the same time relieving congestion, reestablishing flow of blood through

the tissues, aiding in phagocytosis and stimulating repair.

All of these surmises presuppose, of course, free incision and drainage, a thing most important in treating any form of sepsis. One cannot hope to get drainage without it, and it is specially important in this form of treatment. The gross pus, fibrin, and dead and sloughing tissue will be softened and drawn into the saline solution first by the process of diffusion. Then will follow a milking of the intercellular spaces where the active inflammatory process is going on. Pus bacteria, toxic lymph and serum will all pass out into the solution.

As said before, it is not necessary to kill the bacteria if they can be gotten out of the tissues.

The hypertonic solution of sodium chloride or magnesium sulphate should not be too strong. It is an open question which is better. For practical purposes, about $1\frac{1}{2}$ or 2 teaspoonfuls to the pint of hot water is sufficient. If the solution be too strong it may conceivably, and I believe it does, damage cells, by the excessive differences in osmotic pressure.

As for the practical application of this principle of treating sepsis in tissue, the following facts have been found important: First, as to the types of infections that lend themselves best to this treatment, we have found acute streptococcic infections, as lymphangitis, or cellulitis, specially benefited by the treatment. If it be an extremity where soaking is practical, the whole foot is immersed in the hot saline. If it be on a part of the body where this is impossible, hot wet saline compresses are used.

Deep-seated infections where drainage has been established seem to respond nicely to this treatment. Many times in these infections instead of using rubber tubes or tissue for drainage we have used vaseline or dry gauze for drainage, hoping to get the benefit of capillary attraction in aiding drainage toward the surface, remembering nature's lead of trying to throw

off foreign bodies from tissues by reversal of lymph and producing watery suppurating discharge.

In closed or semiclosed cavities this principle of treatment works admirably. Some of you are familiar with the newer closed methods of treating empyema. By using normal or hypertonic salt solution empyema cavities by these methods are rapidly cleansed of pus, fibrin, and rendered sterile in a few days.

I am sure most of us have used hot saline solution for irrigations and gargles. The principle applies here certainly. Not only by osmosis, but by stimulation of mucous glands about the nose and throat by the hypertonic solution, is drainage and relief of congestion obtained.

More recently I have used the idea in irrigating bladders and posterior urethras for prostatic inflammation or abscess formation with amazing results.

We have formed the habit of using stronger solutions for treatment of unopened, deep-seated infections, as in adenitis, synovitis, tenosynovitis, or even arthritis, with good results. I do not mean to convey the idea that there will be drainage through unopened skin in these cases, but the result does seem to be more effective by using saline soaks than by simply using hot water. It does seem to

hasten pus localization in case the infection is going to lead to this, or absorption of inflammatory products in case the infection is not going to localize, but disappear.

The time element also seems important. The soaking or application of compresses should be kept up for at least one-half to one hour, and repeated twice or three times a day.

To summarize: There has always been a vain search for an agent which would be an ideal germicide in treating infections. Many useful ones have been found but all have their objectionable points. Remembering nature's laws of osmosis, dialysis and diffusion, and how important a part inorganic salts play in the life of cells in regulating the osmotic pressure of the cell fluid and intercellular fluid, it seems logical to conclude that using hypertonic salt solution as a soak, irrigation, or compress for infected tissue will result in a reversal of flow of tissue fluids into the solution, thereby ridding the tissue of bacteria and their liberated toxins, as well as relieving congestion and aiding healing. This has been found true clinically.

This method is not offered as a panacea for all infectious processes, but seems to offer many advantages over the use of antiseptics.

SHOULDER PAIN*

MATHER CLEVELAND, M.D.

NEW YORK

IN order to reach an understanding of the various lesions responsible for shoulder pain, some conception of the anatomy and physiology of the shoulder joint is essential.

I propose to review some of its anatomic features, using specimens recently prepared in the department of anatomy at Columbia University.

The shoulder joint is an enarthrodial diarthrosis, or ball-and-socket joint, with motion in three planes at right angles to each other. The articulating surfaces are the rounded head of the humerus and the shallow pyriform glenoid fossa of the scapula. At first sight one can readily appreciate the fact that the glenoid fossa does not accommodate or embrace the humeral head and the joint is therefore not a stable one by its conformation. The capsule is a loose structure attached around the circumference of the glenoid and the anatomical neck of the humerus. In a macerated preparation there is considerable play between articular surfaces owing to the length of the capsule. The ligaments of any joint are merely thickenings or reinforcements of the capsule in response to stress and strain. The capsule of the shoulder joint is reenforced in front by the three gleno-humeral ligaments because the greatest strain is placed upon the capsule by hyperextension of the arm. The capsule is further strengthened by the coracohumeral ligament which extends from the base of the coracoid process of the scapula to the greater tuberosity of the humerus.

The two projecting bony processes of the scapula, the coracoid and acromion, connected by the coracoacromial ligament serve as an extra socket for the head of the humerus. They tend to protect the joint from minor injuries and in a measure

keep the deltoid muscle off the capsule. (See Figs. 1-4.)

MUSCLES

The joint is surrounded by powerful muscles whose balanced tone keeps the articular surfaces in contact. One has only to observe a shoulder joint affected by poliomyelitis, with the humeral head falling well below the acromion process, to appreciate this action of the musculature in stabilizing the joint. Of the muscles acting on the shoulder joint we recognize six groups by their action; there is, of course, some overlapping of function in certain muscles:

1. Abductors: deltoid and supraspinatus.
2. Adductors: pectoralis major, teres major, latissimus dorsi, etc.
3. Medial rotators: subscapularis, etc.
4. Lateral rotators: infraspinatus and teres minor.
5. Flexors or protractors: pectoralis major, biceps, coracobrachialis, serratus anterior, etc.
6. Extensors or retractors: latissimus dorsi, teres minor and infraspinatus.

It is, however, a great mistake to award to one muscle a single isolated action. The cortex thinks in terms of an action, not in terms of this or that muscle or group of muscles, and, the action being determined, a group of muscles is summoned for its fulfilment.

The relation of the long head of the biceps to the shoulder joint should be noted. It passes as a rounded tendon through the intertubercular groove beneath the transverse humeral ligament across the joint to insert into the supraglenoid tubercle. It is invested with synovial membrane. From its situation it acts to prevent the humeral head from being displaced either upward or downward.

* From the clinic of the New York Orthopaedic Dispensary and Hospital. Read before the Clinical Congress of the Connecticut State Medical Society, Sept. 1928.

Injury to this tendon is occasionally the cause of a disability in a baseball pitcher.

FIG. 1. Shallow pyriform glenoid fossa of scapula with tendon of long head of biceps attached to supraglenoid tubercle above and long head of triceps attached below. Deltoid attached to acromion and clavicle is reflected, showing supraspinatus muscle directly over glenoid fossa.

MOTION AT THE SHOULDER JOINT

The shoulder joint is extremely dependent on other joints for its motion. The

FIG. 2. Small shallow glenoid fossa in relation to rather large rounded humeral head. Tendon of long head of biceps is shown in relation to glenoid and humeral head. (From Spalteholz.)

scapula takes part in almost all its motions, sharing in it from the start and not waiting

until the full range of shoulder joint is accomplished.

Adduction with the arm hanging at the

FIG. 3. Capsule of shoulder joint from front. Its attachment to circumference of glenoid and to anatomical neck of humerus may be seen. Extra socket formed by coracoid and acromion processes of scapula connected by coracoacromial ligament is shown. capsule interferes. Forward and backward motions are checked by the acromion process. Rotation with the arm abducted is about 90°.

CONTRAST OF SHOULDER AND HIP JOINTS

While the motion of the shoulder joint itself is not extensive, the arm enjoys an extremely wide range of motion, which leads to a brief contrast of the pectoral and pelvic girdles. We find in the hip joint the femoral head deeply socketed in the acetabulum formed by the three bones which comprise the pelvic girdle, the ilium, ischium and pubis. There is an actual negative pressure which resists an attempt to dislocate the joint and it is morphologically stable. The pelvic girdle is solidly joined to the trunk by the large stable sacroiliac joint, which in most instances has little, if any, mobility. The posterior or inferior extremity is therefore ideally designed for stability in weight-bearing. The range of motion possible in the hip joint is increased considerably by the long neck of the femur which props the inferior extremity away from the side of the body.

In contrast to this tremendous stability in the hip joint and pelvic girdle, we see the shoulder or pectoral girdle attached to the trunk mainly by muscles, its only articulation being the sternoclavicular joint. The clavicle, acting as a prop to hold the extremity away from the side of the body, increases the range of motion possible in the shoulder joint and scapula. This mechanism is quite ideal to serve the tactile and prehensile fingers with a wide range of motion. In a word, the contrast may be summed up as stability versus mobility.

NERVE SUPPLY

The shoulder joint receives its nerve supply through the suprascapular, axillary and subscapular nerves, mainly from the fifth and sixth cervical roots.

BURSAE

A bursa is primarily a shock absorber situated between a bony point and the skin or between a bone and a muscle or its tendon. There are a varying number of bursae adjacent to the shoulder joint.

There may be one beneath any or all of the muscles inserting into the tuberosities. Of the more constant bursae we find:

FIG. 5. M. McG. No. 89840. 1926. Dislocation of right humerus, of six weeks' duration, in woman aged seventy. Severe pain and inability to abduct arm. Head of humerus is seen below and in front of glenoid fossa.

1. The subacromial or subdeltoid is the largest, situated between the capsule and the coracoacromial ligament and acromion process, extending beneath the deltoid muscle.
2. The subcoracoid bursa lies between the coracoid process and the beginning of the coracohumeral ligament and capsule.
3. The subscapular bursa lies between the tendon of insertion of the subscapularis muscle and the capsule.

To summarize briefly the anatomical setting of the shoulder joint, we may note that it is a shallow ball and socket joint with a loose capsule, unstable in itself, depending for support on the surrounding musculature. Its apparent wide range of motion is largely due to the movement of the scapula and rest of the shoulder girdle.

PAIN FROM EXTRA-SHOULDER LESIONS

In dealing with shoulder pain we find a very considerable number of extra-shoulder lesions which are responsible for pain in the shoulder joint. The literature abounds

with instances of these. The phrenic nerve arises from the third, fourth and fifth cervical nerves and pursues a long

ing himself, for over a year, considered in turn neuritis, myositis, bursitis, arthritis, etc., which proved to be intradural tumor

FIG. 6. Scapula in which a new shoulder joint has been made by unreduced dislocation of head of humerus.

course through upper thoracic aperture between the pleura and pericardium to spread out over the diaphragm. When we recall that the nerve supply of the shoulder joint is from the fifth and sixth cervical nerves we see the intimate connection between these nerve paths. Cardiovascular lesions, pleural and pulmonary and mediastinal lesions and intra-abdominal lesions are frequently the cause of shoulder pain. Much has been written of this symptom in gastric and duodenal ulcers, gall bladder disease and even in ruptured ectopic pregnancy.

Conditions of a neurological nature, involving the fifth and sixth nerve roots directly, are also described. Cervical Pott's disease, arthritis of the cervical spine and cervical ribs may cause the phenomenon of shoulder pain. One of my colleagues, a neurologist, recently told me of a case of severe shoulder-joint pain which had been treated by a number of physicians, includ-

involving the fifth and sixth cervical roots. Surgical removal was followed by subsidence of symptoms.

PAIN FROM LESIONS WITHIN THE JOINT

Pain due to lesions within the shoulder joint or adjacent to it affords opportunity for a number of observations. I was impressed with two recent papers on this subject by King and Holmes.¹ In a series of 450 painful shoulders studied by them, the roentgenograms were negative in 300. Of the remaining 150, nearly two-thirds were fractures or dislocations, with infections of various types supplying the other third. I should like to emphasize one point which they made, namely, that a negative roentgenogram is of little value

¹ King, J. M., Jr., and Holmes, G. W. Diagnosis and treatment of 450 painful shoulders. *J. A. M. A.*, 89: 1915, 1927.

Review of 450 roentgenograms of the shoulder. *Am. J. Roentgenol., & Rad. Therap.*, 17: 214, 1927.

in attempting to rule out arthritis or bursitis because the lesion is frequently entirely in the soft parts.

and pain and disability in time disappear. Recurrent or habitual dislocations of the shoulder, where the capsule repairs imper-

TRAUMA AS A CAUSE OF PAIN

Dislocation. Of all large joints the shoulder is perhaps more frequently dislocated than any other. As we have noted, the shoulder relies for support on muscle tone. The accident happens so rapidly that the muscles are taken off their guard and this support is lacking. Most of these dislocations occur with the arm abducted and extended, and the tear in the capsule occurs at its lower part with the humeral head precipitated downward, inward and forward beneath the coracoid process (Fig. 5). Occasionally these are never reduced and the humeral head remains dislocated, with a stiff and painful, limited arc of motion for the extremity (Fig. 6). With a simple dislocation properly reduced, the rent in the capsule tends to repair,

fectly, form a problem of grave importance. The multiplicity of operative procedures recommended for this painful disability bears eloquent testimony to the serious nature of the task.

Fractures of the anatomical neck and of the greater tuberosity are of frequent occurrence and occasionally are coincident with dislocation (Figs. 7-9). It is unwise to attempt to reduce a dislocation without having a roentgenogram of the shoulder if this is possible to obtain.

While on the subject of fractures, one frequently sees a stiff and painful shoulder following prolonged immobilization or disuse of the shoulder joint following a nicely reduced Colles' fracture. Any patient beyond middle age with a fracture of the

upper extremity should exercise the shoulder joint as often as possible. If the joint has to be immobilized, full abduc-

tion should be considered the position of choice.

Bursitis is middle ground between trauma and infection. Any of the adjacent bursae may become inflamed but the one most often involved is the subdeltoid or subacromial bursa.

Subdeltoid bursitis seems to fall into two types. In the first type an initial trauma: a small tear in the tendon of the supraspinatus muscle sets up an inflammation. In the other type infection *per se* seems to play the important rôle. A chilling of the shoulder such as might follow an automobile ride is followed by the characteristic symptoms, pain on abduction of the arm and tenderness over the bursa.

The tender spot disappears when the arm is abducted fully and the bursa rolls beneath the acromion process. On lowering the arm as it passes 90° there is a painful catch as the bursa rolls out again. During the acute stage these patients are most comfortable with the arm abducted. In most acutely painful shoulders, the position of abduction gives tremendous relief and abduction together with traction is frequently advisable. In the chronic stage at times calcifications form within the bursa and their operative removal has been recommended. In our hands the benefit from this procedure has been insufficient to warrant its use. These calcifications tend to disappear with the subsidence of symptoms. (See Figs. 10-13.) Our treatment is conservative, with attention paid to the various foci of infection which may be at fault.

Neuritis. A true neuritis affecting the shoulder joint would involve the fifth and sixth cervical nerves through the suprascapular and axillary nerves principally. This is occasionally seen following trauma such as cutting, tearing or gunshot wounds, fractures or dislocations. Pressure from a cervical rib or a crutch may be a factor to be reckoned with.

Myositis. A traumatic myositis such as follows a tear of the deltoid muscle is an extremely painful disability.

INFECTIONS

Tuberculosis. Of the specific chronic infections of the shoulder joint tuberculosis occasionally occurs, but the incidence is small. The weight-bearing joints are invaded by the tubercle bacillus about nine times as frequently as are the non-weight-bearing joints. The presence of tuberculosis is manifested by pain, spasm, atrophy, proceeding to actual destruction of the joint. (See Fig. 14.) The local manifestation is almost invariably evidence that the patient has tuberculosis in active or latent form elsewhere. The treatment is primarily rest, and the most effective means of securing rest in the joint is by operative fusion.

Osteomyelitis. Among the acute suppurative infections of this region is osteomyelitis of the upper extremity of the

lized at 70° to 80° of abduction, 45° of medial rotation and of flexion, as this is the most useful position.

FIG. 10. September 2, 1928. Patient came to hospital complaining of steady severe pain in left shoulder for two or three days and occasional pain for one month previous. X-ray shows two calcifications within subdeltoid bursa.

FIG. 11. September 14, 1928. Symptoms unchanged, calcifications increased in size and decreased in density.

FIG. 12. October 1, 1928. Very little pain in shoulder. Large calcification has wholly disappeared and smaller only persists as minute spot.

FIG. 13. October 19, 1928. Shoulder now symptomless. Large calcification gone, small one still present.

FIGS 10-13. F. F., male aged thirty-two. Series showing rapid disappearance of calcifications within subdeltoid bursa in a month and a half, while massage and rest in a sling was only therapeutic measure employed.

humerus. If this is not promptly drained it will extend into the shoulder joint and destroy it (Fig. 15). If the shoulder joint has been destroyed and bony ankylosis is anticipated the arm should be immobi-

Arthritis. One approaches the subject of arthritis with a feeling of deep humility when we pause to realize how little we physicians are able to help the arthritic. A large percentage of those patients who

come to us complaining of pain in the shoulder joint will be suffering from arthritis of one form or another. Our dispen-

type. Elimination of the foci of infection seems to have little or no effect. The proliferative type of arthritis, with marked

FIG. 14. R. S. No. 40603. 1927. Tuberculosis of right shoulder joint in ten-year-old boy; severe pain, atrophy and muscle spasm. Destruction of humeral head is to be noted.

saries are crowded with this army of arthritics, a few are helped here and there but the bulk of them pass from clinic to clinic seeking the relief which they seldom find.

The patient complains of a painful shoulder. On examination there is crepitation within the joint, a little spasm on motion, and some atrophy. The roentgenogram may show a few spurs, or may be quite negative. The acromioclavicular joint is often the first in the shoulder girdle to show these changes. This is the arthritis of middle age, the so-called degenerative

FIG. 15. J. McC. No. 93247. 1926. Result of suppurative arthritis of shoulder joint in boy of thirteen years. Disease was acute ten years previously. X-ray shows irregular reparative changes consistent with residual sepsis.

atrophy, pain and often pretty complete disability in the shoulder joint, one sees less frequently. In this type the foci of infection are of very great importance and must be carefully studied.

In closing this discussion I frankly admit that I have made no attempt to present an exhaustive treatise on shoulder-joint pain. I have omitted doubtless many important causes of this symptom and perhaps stressed some unimportant facts. As physicians we must not lose sight of the individual with the pain, in our effort to analyse this symptom. The shoulder joint is a beautiful mechanism, admirably adapted for its intended purpose, but it is not isolated and its pains and aches are not isolated problems but are intimately bound up with the welfare of the patient who consults us.

SIMPLIFIED METHOD OF TRACTION FOR FINGER FRACTURES*

WILTON H. ROBINSON, M.D.

PITTSBURGH, PA.

THERE are so many devices for finger traction that it is difficult to keep an adequate assortment available among the supplies of the surgeon. The routine use of a wire splint imbedded in a plaster-of-Paris splint in the palm simplifies the problem very much. It entails a minimum of advance preparation and almost no expense. The method is not a new one but the particular device described here offers some refinement of detail which makes for efficiency of the traction force and comfort of the patient. It is applicable to recent fractures or to those requiring open reduction.

FIG. 1. Blank splint.

able among the supplies of the surgeon. The routine use of a wire splint imbedded in a plaster-of-Paris splint in the palm simplifies the problem very much. It entails a minimum of advance preparation and almost no expense. The method is not a new one but the particular device described here offers some refinement of detail which makes for efficiency of the traction force and comfort of the patient. It is applicable to recent fractures or to those requiring open reduction.

Finger traction is indicated in fractures

of the shafts of the fingers in those cases in which the palmar splint does not hold the fragments in good position. It is

in diameter in 4 foot lengths. This is known to the trade as Bessemer steel rod. If this is not available ordinary iron

FIG. 3. Wire splint as used for thumb. Position of wire in plaster hand piece shown by black lines. Note angulations of upper wire to conform to palm.

wire may be used. Copper is not so good on account of its malleability. It is well to prepare in advance a number of blanks processed as follows: Cut the rods in 15 inch lengths, place each length at its middle in the jaws of a small monkey wrench (jaws of which should be about $\frac{3}{4}$ inch wide) and bend the two extremities sharply downward so that they lie along the handle of the wrench. Thus is formed a sharp angled U about $\frac{7}{8}$ inch wide and about 7 inches long; this can be easily adjusted to fit any adult finger. These blanks should be kept with the fracture supplies for use as occasion arises.

The method of application of this type splint may be made very simple, but there

are several details that should be meticulously observed:

1. Apply the splint early before the initial clot commences to organize.

2. Attach the longitudinal adhesive strip (which holds a double traction cord) to the anterior and posterior surface of the thumb or finger so as not to make pressure on the edges of the nail, also prevent adhesion of the plaster to the nail by a little powder or gauze.

3. In making the plaster hand piece fold the plaster bandage over and over to make a plaster splint the width of the palm and twice as long and do not put padding on the upper surface.

4. Lay the plaster splint on the palm and wrist and place ends of splint thereon (after bending to conform to shape of palm) so that the side bars are lying along the side of the finger or thumb and extending about an inch beyond.

5. Fold over the piece from the wrist and press it tightly to the palmar section, thus embedding the ends of the wire.

6. Attach a piece of adhesive plaster between the bars of the splint to support the thumb or finger on its anterior surface.

7. Bandage hand splint snugly to hand and allow to set.

8. Make strong traction on cord and tie over end of splint and secure with small piece of adhesive.

Finish the dressing with a finger bandage which starts by turns about the wrist. The use of rubber bands is not to be recommended as the amount of force is indefinite. Also, the use of the Spanish windlass device on the cord from the finger to the end of the splint is not advised because of the possibility of producing rotation of the distal fragment. In a case of multiple fractures additional wire blanks may be incorporated in the plaster hand piece.

CLINICAL AND PATHOLOGICAL ASPECTS OF APPENDICITIS*

BERNARD PORTIS, M.D., PH.D., F.A.C.S.

CHICAGO

THE appendix is the organ most frequently involved of pathological conditions of the intra-abdominal organs. The substance of this paper represents the author's work at the Michael Reese Hospital Pathological Laboratory, his surgical service and association with Drs. Milton M. and Sidney A. Portis in their private practice. The operated cases were from the author's private practice and the surgical wards of the Michael Reese Hospital.

There are certain anatomical facts which I will first consider before delving into this problem. The appendix with the cecum undergoes rotation within the abdomen during embryonic development. Early in fetal life the ascending colon is found in the lower left quadrant and gradually takes an upward course toward the splenic flexure and then across the upper abdomen and down the right lateral side until the cecum reaches the right lower quadrant. Here there is a fusion of the peritoneal folds forming a more or less marked mesentery for the cecum. This rotation may assume great importance in locating the appendix when it is not in its normal position. Many surgeons have found appendices in the region of the gall bladder, and in 2 of my cases, the appendix was found under the midportion of the transverse colon in the upper abdomen. The appendix receives its blood supply from the appendicular branch of the ileocolic artery and being an end vessel has very little collateral circulation. During acute inflammations there is an acute edema and swelling of the entire organ. This produces a marked ischemia of the tissues because the inelastic serosal covering does not permit of expansion. These are several of the factors lowering the vitality

of the appendix when once inflamed, and hence increasing the rapidity of the destructive changes. The appendix has a very large amount of lymphoid structures in its submucosa, and has been frequently called the "abdominal tonsil." This latter fact may explain the frequency of acute appendicitis during any acute infectious diseases, and more especially those with involvement of the lymphatic structures elsewhere in the body.

The following are the clinical and pathological divisions of appendicitis:

1. Acute appendicitis:
 - a. Acute catarrhal
 - b. Suppurative
 - c. Gangrenous
 - d. Perforative.
2. Complications and sequelae of acute appendicitis:
 - a. Resolution
 - b. Abscess
 - c. Local or generalized peritonitis
 - d. Subphrenic abscess
 - e. Pyelothrombopheblitis
3. Subacute appendicitis
4. Chronic appendicitis.

The pathogenesis of acute appendicitis is well known, yet there are several features which I wish to emphasize. Most of the appendices become infected through the blood stream from a more or less distant focus, although many cases may have local origin from small ulcers of the appendix, especially associated with fecaliths. The earliest stage, acute catarrhal appendicitis, frequently is associated with a moderate or large amount of serous fluid in the peritoneal cavity which readily escapes on opening the abdomen. The appendix is usually injected and feels swollen and stiffened. One may sometimes find a fibrinous deposit on its surface.

* Submitted for publication June 6, 1929.

The microscopic picture however is very definite, yet many hospital laboratories frequently overlook the early changes.

extensive infarction takes place with the ensuing gangrene or perforation.

There are several possible outcomes of

FIG. 1. Section demonstrating raising of epithelium lining appendix by serofibrinous exudate. First changes in acute catarrhal appendicitis.

FIG. 2. Second stage, illustrating breaking through of epithelial structures and permitting exudate to enter lumen of appendix.

During the earliest stages the most important changes occur in the lymph follicles which become very hyperplastic and enlarged. The lining epithelium is raised by a small amount of fluid which contains fibrin and a few leucocytes. The small vessels in the immediate region are dilated and contain an increased number of leucocytes. The exudate may then permeate the epithelial lining and enter the lumen of the appendix or may infiltrate the deeper structures of the wall. Small ulcers frequently appear in the mucosa allowing a free exit of the exudate into the lumen. A little later in the progressive cases, the suppurative element becomes very prominent and there then results a diffuse involvement of the entire thickness of the organ and if the cecal opening is closed by a fecalith or stricture, the appendix becomes very swollen and develops into an empyema of the appendix. Coincident with this swelling and edema of the organ the blood supply is interfered with, as indicated already, so that more or less

the inflammation. Resolution of the condition is the most favorable and unfortunately does not occur in the majority of cases. If it does take place very little may remain except fibrosis and sometimes partial obliteration of the lumen. However, most of the cases, when the pathology has reached the suppurative stage, rarely subside but produce either a localized abscess or peritonitis. Subphrenic abscess and pyelothrombophlebitis are quite rare but should be kept in mind as late sequelae.

Chronic appendicitis is usually not an inflammatory condition of the appendix as the name indicates, but rather the results of previous acute attacks. The pathological changes which cause the symptomatology might be better described by the surgeon than from studies on the amputated appendices. The usual operative findings are thickening of the wall, more or less kinking due to adhesions, elongation and the presence of fecaliths. Very careful studies of these cases before and after operation has conclusively shown

that the symptoms are usually due to appendiceal colic rather than appendicitis. At the operating table it is quite simple to realize the clinical possibilities, but the microscopical studies show few changes in the wall.

The clinical studies on acute appendicitis are based on 135 cases operated upon by the author from his private service and the ward service from Michael Reese Hospital. Many were neglected cases, seen late after the onset, and frequently had been subjected to drastic purging. In spite of this there were only 4 deaths from overwhelming peritoneal infections. The age factor is of great importance in considering the symptomatology. The pediatricians have separated their cases as those occurring under five and after five. I should like to add to these two divisions a third, as those occurring after fifteen. Appendicitis occurring under five may be very difficult to recognize as the picture is frequently very bizarre and almost indistinguishable from many of the acute infectious diseases. The high mortality in the very young is due partly to the late stages in which the children are seen and secondarily to the rapidity of the infectious process. The omentum is poorly developed in the young, and hence may be an additional factor in the absence of walling off of an inflamed appendix. However, there are many symptoms which are quite common to appendicitis and when these appear in children the diagnosis of acute appendicitis must be kept in mind until it is ruled out.

The onset of acute appendicitis is rarely stormy and when such does occur in an acute surgical condition in the abdomen, the diagnosis of appendiceal involvement should be made with a great deal of caution. Ordinarily the patient or the parents in the case of children will give the fact that there was first a period of several hours of abdominal discomfort. Pain is of variable intensity. In 75 per cent of the cases pain was first generalized and only after several hours did it localize to the right lower

quadrant. The maximum pain may be elsewhere in the abdomen when the appendix is situated in an abnormal position.

FIG. 3. Low power microscopic representation of a well-defined ulcer. Lymphatic follicles are hyperplastic.

In the retrocecal form the patients complained of severe backache and when the underlying ureter was involved secondarily, the symptoms simulated renal colic with red blood cells in the urine. I have seen 3 cases with frank hematuria.

Gastrointestinal distress has never been absent in any case of acute appendicitis I have seen. This may manifest itself simply by anorexia or loss of appetite or be much more severe with nausea and vomiting. The recognition of this distress is of great importance in the diagnosis and may be elicited by careful inquiry into all the subjective sensations from the last period of normalcy before the present illness. Vomiting was present in 77 per cent of all the cases and then was chiefly gastric or biliary.

The temperature was increased in the majority of cases within the first twenty-four hours. This series, however, includes 4 cases which demand special consideration as 4 children experienced a rapid rise in

temperature of 104° F. in the first eight hours and had persistently low leucocyte count. The appendices in these 4 cases were in a gangrenous condition.

The leucocyte count was increased in most of the cases with counts ranging between 15,000 and 20,000 and a definite polynucleosis. This feature is of importance but it should not be made decisive and operation should not be based solely on this finding.

The urine was usually normal except when the appendix was retrocecal, in which case red blood cells were present.

The physical findings were very important, especially that of localized tenderness in the right lower quadrant, and the degree depended somewhat on the nearness of the appendix to the anterior abdominal wall and was least marked with the retrocecal position. Exquisite rebound tenderness, which may be elicited by suddenly letting up the compressing hand, was usually diagnostic of peritoneal inflammation or free peritoneal exudate. Muscular rigidity was the most variable of all the findings and this was especially so in the very early stages. Rectal examination was important in the posterior lying appendices as it was frequently palpated and very tender.

I will not go into the differential diagnosis of acute appendicitis as it would require the consideration of a very large number of intra-abdominal and other pathological conditions for this discussion.

I will just mention treatment in passing to state that I believe in the dictum that once the diagnosis of acute appendicitis is made, operation should be performed without delay, and the appendix should be removed in all cases where it is humanly possible without subjecting the patient to too great a risk.

The symptomatology of chronic appendicitis may be very indefinite and simulate any of the usual chronic diseases of the gastrointestinal tract and biliary system. There are, however, several symptom complexes caused by chronic appendicitis

which should arouse suspicion as to appendiceal source of the complaints. Upper abdominal distress with or without pylorospasm may frequently be referred from the appendix. The underlying pathological changes in the appendix have already been discussed and as it was indicated the appendiceal colic is not dependent so much on mural changes, but is caused by adhesions and kinks about the appendix. The surgeon is frequently impressed with these findings and has noted complete relief after the removal of the appendix. I wish again to emphasize the apparent disparity between the pathological and clinical findings, and believe this may be explained on the abnormal physiology produced by the appendix's inability to expel its contents into the cecum. The finding of localized tenderness over the appendix may help in the diagnosis. The x-ray examination will usually show an elongated, kinked and irregularly filled appendix. Further, tenderness will be over the organ itself as visualized, and often one may produce referred epigastric pain by pressure over the appendix. This x-ray examination should be carried out for several days so as to determine the emptying time of the appendix, as undue delay again speaks for disease.

Chronic appendicitis is not necessarily surgical, but one should caution the patient suffering from chronic appendicitis to avoid sojourning in places where competent surgical attention is not available. The experience of my brothers in the medical treatment of this condition will be emphasized in the discussion. Just to mention, however, that correct dieting and medication to establish better gastrointestinal function with the removal of foci of infection will prevent the majority of these patients from requiring surgical attention.

CONCLUSIONS

The appendix, because of its richness of lymphatic tissue and being a blind pouch-like structure, is very prone to

infection. The progressive nature of the disease is dependent upon its poor collateral circulation, and the vicious tendency of the organ when once inflamed to interfere seriously with its own circulation giving rise to local tissue destruction.

The early microscopical findings of acute appendicitis are early confined to the space immediately under the lining epithelium. Here one finds at first only a fibrinous exudate which later may develop into a purulent condition. This latter may then either invade the wall or enter the lumen through small ulcers. If the appendix is not removed, perforation or gangrene with peritonitis or abscess formation frequently develops.

The recognition of acute appendicitis depends upon the sequence of symptoms of abdominal pain later localizing in the right lower quadrant, gastrointestinal distress, increased temperature, localized tenderness over McBurney's point and leucocytosis.

Chronic appendicitis as a clinical entity usually does not signify the presence of a chronic inflammatory process but symptoms due to adhesions and kinking of the appendix so as to interfere with the normal peristaltic action of the appendix. The clinical picture may simulate any of the chronic inflammatory conditions of the gastrointestinal tract or biliary tract, and the condition is diagnosed chiefly by local tenderness and x-ray showing elongation, kinking and delay of the emptying time of the appendix.

Acute appendicitis is a surgical condition and the appendix should be removed in all cases, no matter at what stage it is seen, where it is humanly possible.

Chronic appendicitis is not necessarily surgical except as a prophylactic for acute appendicitis attacks. It may be treated in the majority of cases by careful medical management directed toward establishing a normal function of the gastrointestinal tract.

THE SURGICAL IMPORTANCE OF OCCASIONAL COMMUNICATIONS BETWEEN THE SYNOVIAL SACS OF KNEE AND PROXIMAL TIBIOFIBULAR JOINTS*

CARNES WEEKS, M.D.

NEW YORK

CUNNINGHAM'S Anatomy¹ states in describing the proximal tibiofibular joint: "Occasionally there is an opening in the stratum fibrosum by which communication is established between the articular cavity and the knee-joint, through the intermediation of the synovial prolongation subjacent to the tendon of the popliteus muscle (popliteal bursa)."

This communication, though acknowledged by the anatomists, is liable to be forgotten by the average general surgeon and if remembered is considered of but little clinical importance.

As long ago as 1839, before the days of antiseptic or aseptic surgery, it was recognized that exarticulation of the fibula was a dangerous procedure and was usually followed by infection of the knee joint. Gruber,² in 1845, describing communications between these two joints, states that Baron Larrey's method of amputation of the leg, with simultaneous extraction of the fibula, was condemned by surgeons of that time. The reason for such condemnation was the almost unavoidable complication of "inflammation of the knee joint." He also says that the operation of Seutin and Malgaigne for disarticulation of the fibula is open to the same criticism and that a successful operation (non-infection of the knee joint) is rare. He explains this unfortunate complication by the presence of the occasional communication (11 out of 80 dissected by him) between the proximal

tibiofibular and knee joints. In those cases in which there was no communication the close proximity of the two synovial sacs necessitates tearing of the popliteal bursa in exarticulation of the head of the fibula.

In these days of aseptic surgery this criticism is not entirely valid, but that there is still danger of suppuration of the knee joint following resection of the fibula is emphasized by the reports of the two following cases:

CASE I. E. B., white male, thirty-seven years old, admitted January 17, 1928 for treatment of painful amputation stump. Fifteen years before he was run over by a train, necessitating amputation through the upper third of the right leg. He had been using successfully an artificial leg but for the past few weeks complained of painful stump. Physical examination showed amputation of right leg 6 inches below the knee with stumps of tibia and fibula the same length, with a small ulceration over the distal extremity of the fibula. One week later the ulcer was carbolyzed, and 1 inch of the tibia and all the remainder of the fibula were removed through a curved incision over the end of the stump. Twenty-four hours later, the patient developed a hemolytic streptococcus infection of the right knee joint. At this time a mid-thigh amputation was done. Following this the patient made an uneventful recovery. Dissection of the amputated extremity showed infection of the bed of the fibula extending directly into the posterior portion of the knee through the popliteal bursa. Because of the severity of the infection it could not be determined whether the communication between the two synovial sacs was natural or artificial.

CASE II. H. K., male, aged forty-three, admitted April 9, 1928 complaining of painful

an amputation of the left leg below the knee. He had used an artificial limb in spite of severe pain for past two years. Physical examination showed an amputation through the upper third of the left leg, both bones of equal length and a small ulcer over the stump of the fibula. Four days later following carbolic acid of the ulcer, a lateral incision was made and the entire fibula removed, following dissection of the tibiofibular joint attachments. A small pocket of pus was discovered over the distal extremity of the tibia. This was drained. Six days after operation the patient developed a hemolytic streptococcus infection of the left knee joint. Arthrotomy was performed and Wilms treatment instituted. At this operation an oval communication between the knee joint and the old tibiofibular articulation was discovered. Patient continued to do badly and five days later a left supracondylar amputation was performed. Patient made an uneventful recovery.

amputation stumps of the upper third of the leg. Both cases had small chronic ulcers present over the extremities of their stumps. Both had their stumps revised with exarticulation of the fibula. This was done according to the recommendation of Heitz-Boyer, who advised removal of the fibula in painful amputation stumps of the leg. Infection was present in each case in the form of chronic ulceration. Acute suppurative arthritis of the knee joint followed postoperatively, in each case necessitating amputation through the thigh. In both specimens open communication was found between the knee joint and the tibiofibular joint.

The similarity of these cases and the results of surgeons before the days of aseptic surgery can hardly be overlooked. The infection travelled up the bed of the

fibula and through a natural or an artificial opening into the synovial sac of the knee.

Twelve lower extremities were dissected

FIG. 3. Cavities separated by only two layers of synovial membrane. Injection fluid present in tibiofibular joint is seen through floor of popliteal bursa. This condition is present in the majority of cases. 1. Cut edge of popliteal bursa. 2. Proximal tibiofibular joint. 3. Injection fluid.

in the anatomy department. Methylene blue was injected into the synovial sac

of the proximal tibiofibular joint. In 4 of these 12 dissections a communication was discovered. In each of these cases the knee joint contained the dye. In the 8 which showed no such communication the striking fact determined was the close proximity of the two synovial sacs. In all, the prolongation of the popliteal bursa overlay the roof of the tibiofibular synovial sac, the two cavities separated only by thin layers of synovial membrane. In such a case removal of the head of the fibula would inevitably involve opening the knee joint through the popliteal bursa.

The anatomy of this region is well described by Henle.¹ He reports that when such communications exist the articular cartilage of the knee joint becomes continuous with the articular surface of the tibiofibular joint. This observation was made in each of the 4 dissections made by the author in which communication existed.

CONCLUSIONS

1. The synovial sacs of the knee and the proximal tibiofibular joints communicate in about 15 per cent of cases.
2. Where no such communication exists the close proximity of the two synovia necessitates injury to the popliteal bursa in exarticulation of the fibula.
3. Acutesuppurative arthritis of the knee joint may readily follow removal of the head of the fibula in the presence of infection.

OPERATIVE INJURY OF THE URETER*

REPORT OF 5 CASES WITH A REVIEW OF THE LITERATURE

AUGUSTUS HARRIS, M.D., F.A.C.S.

BROOKLYN, N. Y.

THE following 5 cases of operative injury of the ureter have come under the observation of the writer during a recent two-year period.

CASE I. Mrs. M. W., aged thirty-eight years, housewife. On November 26, 1926, during a hysterectomy and right salpingo-oophorectomy operation, the lower ureter was accidentally clamped and cut across during the operative procedure.

Immediately following injury the gynecological surgeon performed an end-in-end anastomosis of the ureter, invaginating the lower end of the upper segment into the lumen of the lower segment, and reinforcing the same with fine plain catgut sutures. Three days following this operation there was a rise in temperature, pain in the right kidney region with pyuria with slight hematuria, and the abdominal wound broke down, discharging a large quantity of urine.

Cystoscopic examination on December 10, two weeks after operation, showed some degree of cystitis. Left ureter catheterized normally with return flow of clear urine. The ureteral catheter, however, on the right side was temporarily obstructed at a point about 10 cm. from the bladder. On passing farther up the ureter a catheter entered freely with a return flow of about 100 c.c. of urine with the terminal portion cloudy, indicating a definite hydronephrosis. Function of the left kidney was normal, while the phenolsulphonephthalein test showed a marked delay in function on the injured side. The catheter in the right pelvis was fastened in position for three days with frequent irrigation to relieve the hydronephrotic condition.

A second cystoscopic examination was performed on December 21, eleven days after the first cystoscopy. This also showed a moderate degree of hydronephrosis with temporary obstruction in the right ureter at the same point, 10 cm. above the bladder. There were signs of slight infection at this time but marked improvement. Very soon after the first cystoscopy was performed, the drainage of urine

from the wound was materially lessened. On January 7, 1927, cystoscopy showed a normal bladder, the lumen of the right ureter entirely free with no evidence of hydronephrosis or infection with normal function. The wound healed rapidly from this time on until she was discharged on January 20, 1927 with wound entirely healed.

CASE II. Mrs. S. O'B. was operated upon January 3, 1927 by another gynecological surgeon and, during the removal of a very large ovarian cyst, the left ureter was accidentally severed at a point about 12 cm. from the bladder. In this case the operating surgeon also performed an end-in-end anastomosis, invaginating the stump of the lower end into the lumen of the upper segment and reinforcing with fine catgut sutures. In this instance, also, the wound broke down after three or four days with discharge of urine, and the patient was cystoscoped one week after operation. Temporary obstruction was encountered with a small soft No. 4 olive-tipped bougie at a point 12 cm. from the bladder. This was finally passed and a very moderate hydronephrotic pelvis found, with slight infection. In this instance it was deemed advisable not to leave the catheter in situ in view of conditions of the case. A second cystoscopic examination was done one week later, and a No. 5 and 6 F. catheter were each passed to the pelvis, and about 12 c.c. of hazy urine obtained. Gentle lavage was done with silver nitrate solution 0.5 per cent. The urinary drainage from the abdominal wound gradually subsided and she left the hospital about three and one-half weeks following the original operation, completely healed. Eighteen months after leaving the hospital the patient returned to my office for cystoscopic examination, at my request. She had been entirely well since leaving the hospital, and cystoscopic investigation showed a normal condition of bladder, ureter and pelvis and kidney.

CASE III. Mrs. O. C. on March 3, 1926 has a complete hysterectomy performed by another gynecological surgeon. The operation

* Read before the Kings County Medical Society, May 22, 1929.

was entirely smooth and the operator did not know that the ureter had been injured at the time. Several days later, however, there was

CASE IV. Mrs. H. K., aged forty-eight years, married, was admitted to the Long Island College Hospital on May 3, 1927 and

FIG. 1. Pyelogram of Case 1 shows hydronephrosis from ureteral obstruction. Note iodide solution diffused in tissues about lower ureter at site of ureteral injury and fistula. Recovery was later complete.

considerable drainage of urine from the vagina with pain and rise of temperature. Patient was allowed to go for three weeks in hope that this fistula would heal. Urinary leakage continued and cystoscopic examination on March 26, 1926 showed an obstruction to catheter in the left lower ureter only 3 cm. from the ureteral meatus. This could not be overcome by any catheter or bougie. Subsequently a second laparotomy was performed and the left lower ureter was isolated, divided at obstructed point and implanted into the bladder. This healed well and there was no more recurrence of urinary drainage per vaginam. She left the hospital in May 1926 entirely healed but refused all requests for cystoscopic study. We have been unable to ascertain the whereabouts of this patient since that time.

FIG. 2. Ureterogram of Case v with complete block just below renal pelvis at site of ureteral anastomosis.

died of uremia on May 11, 1927. She had been operated upon nine years before, a hysterectomy having been done. Following this operation, urine drained from the vagina for several months but finally ceased. For about a year before admission to the Long Island College Hospital she was under treatment for marked hypertension, and suffered occipital headaches, buzzing in the ears, and paresthesias in the hands and feet. Further examination revealed a high nitrogen retention in the blood, which gradually increased with development of anuria.

Cystoscopic examination revealed an impassable stricture 5 cm. above the left ureteral meatus. A large hydronephrotic mass was palpated in the left loin and upper abdomen. The extreme condition of the patient did not permit of operative procedure. The nitrogen retention continued to increase. The patient lapsed into deep coma and died eight days after admission.

Necropsy revealed an arterio-sclerotic, contracted kidney on the right side, with a very large thin-walled hydronephrotic kidney on

somewhat of the intrarenal type so that free exposure was necessary to facilitate stone removal. Following the operation, the stump

FIG. 3. Fistula in renal wound injected with lipiodol, Case v. Filled pelvis indicates distortion and rotation. Nephrectomy required.

the left side, dilated ureter with complete occlusion of its lumen near the bladder and surrounded with scar tissue. In this instance we have a striking example of the late results of operative injury of the ureter. Unfortunately, the patient had a complicating arterio-sclerotic kidney on the opposite side which did not permit nephrectomy. One is inclined to believe that early implantation of the lower ureter into the bladder following the hysterectomy operation, when the vaginal fistula developed, would have prevented the ureteral stricture and resultant destructive hydronephrosis.

CASE V. Mr. R. C., aged forty-four years, married, had a pyelotomy performed by the writer on August 27, 1928, for a large stone in pelvis (about 2.5 by 3 cm.). During this procedure, while removing a large amount of dense, adherent, fibrofatty exudate from the posterior renal pelvis, the ureter was completely divided at its junction with the pelvis. The pelvis was

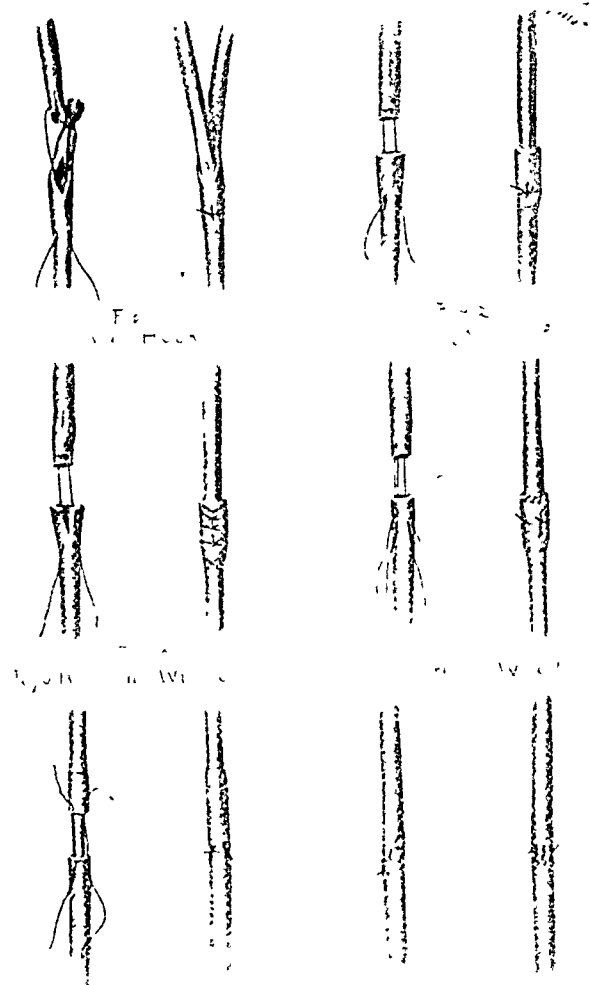

FIG. 4. Few of more commonly employed methods of ureteral anastomosis. (After Sharpe.)

of the ureter was very carefully sutured to the pelvis, telescoping the divided ends, placing the ureter within the cavity of the pelvis, and suturing from without with No. 00 plain catgut. A flap of fat was further sutured around this area for protection. There was temporary drainage from this ureter into the bladder as was proved by cystoscopy and the ureter catheter. Urine, however, continued to drain in considerable quantity from the wound in the flank, and attempts to drain the pelvis with an in-dwelling catheter failed.

Cystoscopic examination on September 10 showed that there was complete obstruction in the ureter at a point 22 cm. from the bladder with no return of urine from the catheter.

Ureterogram showed complete occlusion of

the ureter at this point so that no iodide solution entered either the pelvis or the urinary fistula in the flank. Injection of the wound

and pelvis resulted successfully. In one of these Dr. Hamilton Bailey encountered a complete divulsion of the pelvis from the kidney.

FIG. 5. Diagram of magnesium tube of Prof. Taddei with No. 0 catgut sutures in place, ready to be inserted into ureteral lumen.

with lipiodol solution showed an odd type of pyelogram with rotation of pelvis and considerable solution in the surrounding spaces. Left nephrectomy was, therefore, performed on October 4 with an uneventful recovery.

The kidney was found to be surrounded with extensive, dense adhesions and scar tissue, which could not be liberated from kidney excepting by the use of bold, free dissection with curved scissors. The kidney in the gross seemed to be in fairly good condition. The ureter near the pelvis was found to be converted into a firm cord for a distance of about 5 cm. Section of the kidney removed showed multiple abscesses with infiltration, fibrosis, and with atrophy of the parenchymatous elements.

C. H. Peck has shown the importance of "splinting the ureter" by a catheter passed down the ureter to prevent post-operative obstruction after plastic operations upon the renal pelvis, and even after kidney suspension operations. This catheter is brought out through a stab wound in the kidney and out of the wound in the flank, remaining in position for several days. Two similar cases are reported in the *Journal of Urology* of the present year (1929) by two different urologists, in which anastomosis of the ureter

COMMENTS

The relative frequency of these cases, together with the interesting problems involved, has prompted me to make a study of the literature upon this important subject. A thorough study proves that operative injury of the ureter is by no means a rare condition. In fact, it is probable that a relatively large number of cases, occurring in the hands of individual operators, never find their way into print. This is borne out by statements of eminent authorities such as Baldy, Culbertson and others. In 1925 Bland collected 316 cases from the literature and also gathered 125 additional cases from surgeons actively engaged in abdominopelvic work, making a total of 441 cases. The 125 cases were reported from forty-two surgeons, making an average of 3 each. Bland, himself, stated that he injured the ureter six times over a period of fifteen years. Of the total series of cases 360 were unilateral and 81 bilateral. It is worthy of note that frequent operative deaths attributed to "suppression of urine," particularly in radical pelvic operations of former years were, no doubt, the result of ureteral occlusion. Fortunately, many of the radical operations for carcinoma of the uterus, where accident is most likely, are being abandoned. Injury occurs most frequently during gynecological procedures, especially hysterectomy, less often during urological or other abdominal procedures. Ligation is said to be the first in point of frequency, clamping second, and incision by scissors or knife third. The clamp is usually followed by sloughing. Ligation, if unilateral, may go unrecognized. In this connection it is interesting to note that Barney, in ligating one ureter in 37 animals, found that anuria with renorenal reflex did not occur once. The ureter has also been injured during simple vaginal

drainage, and in difficult forceps delivery cases. Injury is most likely to occur during ligation of uterine and ovarian vessels.

obviously cannot be foretold. In Case iv of this series practically complete obliteration of renal tissue with extreme hydrone-

FIG. 6. Taddei's magnesium tube in position for anastomosis, sutures passed through ureteral walls, larger bite of ureteral stump taken in vesical end.

The writer cannot stress too strongly the importance of early cystoscopy in all cases where ligation or other injury is suspected. In some instances it may not be detected until an abdominal or vaginal fistula develops. In all of these cases immediate cystoscopy may be the means of saving a kidney which is otherwise doomed

phrosis resulted nine years after operative injury. Brown mentions one instance of a thin kidney cortex with secretory activity ten years after complete obstruction. He also reports an instance of removal of suture which accidentally ligated the ureter with recovery of the patient. In another case, ureterovesical implantation

FIG. 7. Taddei's tube in position with sutures A-A' and B-B' drawn taut, B-B' tied and A-A' about to be tied. Note renal stump invaginated into vesical stump with magnesium tube acting as splint.

to destruction. Caulk and Fisher report a case of double nephrostomy done on the eighth day after injury with recovery of the patient. In this instance complete repair of the wounds was accomplished on the fifty-eighth day. Furniss reports a case in which both ureters sloughed after clamping for the short period of seven to eight minutes. The slough manifested itself on the eighth and twentieth days on each side.

The end-results of operative injury

resulted successfully after severance of the ureter.

In injuries at the lower end of the ureter, ureterovesical anastomosis is, probably, the one of choice. The report of A. Petersen based upon 21 dog experiments and 21 human cases concludes that a "normal or almost normal kidney and ureter should result following implantation of the ureter into the bladder." At higher levels the uretero-ureteral anastomosis should be done by one of the various methods, pro-

vided the severed ends can be brought into apposition with sufficient relaxation of the rest of the duct. End-to-end anastomosis

means of saving the kidney, even though ureterovesical implantation might have been required.

FIG. 8. Result of Taddei's magnesium tube method of anastomosis. Note normal appearance of ureters, pelvis and kidney. Autopsied dog showed no pathological results.

FIG. 9. Photograph of kidneys and ureters of dog killed nine months after operation. A. Site of suture of right ureter. This shows excellent result of end-to-end suture after employing side slit drainage of urine above area of anastomosis. (Courtesy Drs. Bump and Crowe.)

with invagination, after the method of Poggi or Van Hook, is the most popular. H. H. Young recommends end-to-end suture over an indwelling ureteric catheter.

Considerable success has been met with clinically in uretero-ureteral anastomosis. The reason for this is the remarkable power of repair of the ureter. This fact is, probably, not fully appreciated. Ultimate success depends almost wholly upon the maintenance of canalization of the lumen. Temporary hydronephrosis and infection resulted in 2 of my cases due to temporary obstruction which was readily overcome by follow-up cystoscopic procedure. In Case iv we feel rather definitely that cystoscopy done when the ureterovaginal fistula developed would have been the

The basis of results in ureteral injury and repair are to be found in numerous dog experiments. Joannides and Holmes proved, in 17 experiments, that tubulization of the ureter would take place with healing around an in-dwelling catheter even when a gap of 1 or 2 cm. was intentionally left between the severed ends. In only 2 of these did hydronephrosis develop. Where a gap is left, however, stenosis is more likely to take place. These writers, in 1925, state: "uretero-ureteral anastomosis should be the method of choice if one could have a rigid mechanism for keeping the lumen patent until complete healing takes place." These authors, are, no doubt, unmindful of the fact that just such a piece of most excellent and successful work has

been done. I have been unable to find any reference in the English literature to it except the mention of the method in the book of Thomson-Walker. I refer to the 6 dog experiments of Professor Domenico Taddei of Florence, Italy (1904) whose work has been translated for me. He uses a perforated, soluble tube of magnesium in the lumen of the severed ureter. Its length is 1 cm., calibre 1 to 3 mm., with thin walls and with rounded, tapered, oblique, parallel ends. His studies are complete and reveal 100 per cent success, even histologically, in the ureter and kidney of all cases. In none was any trace of the magnesium found after twenty days. I have communicated with the author with the hope of further knowledge and studies in this important contribution to urological surgery.

One of the earliest operations of ureteral anastomosis was that of Simon in 1851 at St. Thomas' Hospital, London. A large percentage of the earlier cases on record were rectal implantation of the ureter for exstrophy of the bladder. To our own Coffey belongs the credit for perfecting the technic of rectal implantation.

Alksne, 1908, collected all the reports of uretero-ureteral anastomosis and found 43 complete recoveries in 60 cases, 9 recoveries after temporary fistula and 8 deaths (mortality 11.6 per cent). In 1887 Poggi reported 2 successful cases of ureteral invagination in dogs, which, when autopsied, showed no stricture. His method, since that time, according to Alksne, showed the best results; 12 per cent of fistulae occurred in 28 cases, while the circular method showed 24 per cent of fistulae.

Van Hook's experiments in dogs, reported in 1893, are also an interesting and valuable contribution. Sampson has shown further that the ureter will stand considerable manipulation, even to stripping. Margavucci, also, isolated the entire ureter in 10 dogs without resulting necrosis. He believes that the blood supply from the renal artery is almost sufficient. He has taught us the valuable point in all ureteral work, that special care must

be exercised in all cases to conserve the periureteral arterial plexus.

Arthur H. Curtis has recently shown a

FIG. 10. Pyeloureterogram of patient five months after anastomosis of severed ureter. P, Normal kidney pelvis. A, Site of ureteral anastomosis. Clinical case of Dr. Arthur H. Curtis who successfully employed method of Bump and Crowe with side slit drainage of urine above line of suture.

very successful result of uretero-ureteral anastomosis in the human after the method of Bump and Crowe, which method at this writing has not been published. As suggested by L. L. McArthur, the urine is temporarily drained through the flank by a catheter passed through a slit in the ureter above the site of anastomosis.

The methods of anastomosis, as given by Thomson-Walker, are listed as follows:

- (1) End-to-end
 - (a) Horizontal
 - (b) Oblique
- (2) End-to-end (Poggi)
- (3) Special soluble magnesium tube (Taddei)
- (4) Invagination method of Van Hook

(5) Lateral anastomosis with ends closed. The author states it is well to cover the area of repair with fat tissue to aid closure.

it, end-to-end anastomosis with invagination, or ureterovesical implantation, should be done according to the level of the injury.

FIG. 11. Case iv. Autopsy specimen. Arrow indicates point of complete strictural obstruction with dilated ureter above with large hydronephrotic pelvis and kidney. Note lobulated appearance of thinned sac-like renal cortex. Opposite kidney shows granular contracted appearance of arteriosclerotic kidney. Result of surgical injury of ureter nine years before.

FIG. 12. Case iv. Longitudinal section of lower ureter. Arrow indicates strictured ureter with dilation above. Note also darker hemorrhagic appearance of mucosa below area of stricture resulting from instrumental attempts during previous cystoscopy to pass point of obstruction.

Bickham discusses sixteen different operations of ureteral anastomosis. These fall into two general groups:

- (1) End-to-end
- (2) End-in-end.

A case of lateral anastomosis of a double ureter was successfully and ingeniously employed by Foley for the relief of obstruction in one of the branches of a bifurcated ureter. I have taken the liberty of reproducing diagrams of the various methods employed.

During surgical procedures, special care should be exercised in isolating the ureter, particularly in difficult pelvic work. In some instances, the in-dwelling ureter catheter may be very helpful. When accident occurs, and the operator knows

Repair is best done at the time of accident, provided the surgical condition of the patient warrants, without jeopardizing the patient. If not, the ureter must be brought out upon the abdominal wall temporarily, or preferably through a stab wound in the flank, until further repair work can be done. Nephrectomy is, usually, the last resort in all instances, although in certain cases, the kidney must be sacrificed. Where ureters have been ligated, a number have resulted successfully following removal of the ligatures after a short period. In point of identifying the ureter as a definite precaution, Robinson emphasizes the following points:

- (1) Kelly's vermicular contraction test, i.e. stroking the ureter for peristalsis

- (2) Absence of pulsation
- (3) Consistency and thickness of walls
- (4) Attachment to posterior leaf of peritoneum.

CONCLUSIONS

1. Surgical injury of the ureter is far more frequent than commonly supposed.
2. Complete repair should be done at the time of accident, provided the condition of the patient makes it possible.
3. Uretero-ureteral anastomosis with invagination is the method which has been most successful (Poggi and Van Hook methods).
4. The soluble magnesium tube of Taddei appears to be a valuable contribution for successfully canalizing the ureter at

site of injury. This method has evidently not received the attention it deserves.

5. Certain definite principles of identification and isolation of the ureter, if carefully followed, should aid in reducing the incidence of ureteral injury.

6. Early cystoscopy should be done in all cases where ureteral injury is known or suspected. This may be the means of saving a kidney, or even the life of the patient.

7. Cystoscopic exploration of the ureter should be done at intervals, for a time at least, following anastomosis. This depends upon the tendency of the operative area to stenosis.

8. It is worthy of note that the literature upon the surgery of the ureter has increased considerably in the past five or six years.

CASE REPORTS

TUBERCULOSIS OF THE VAGINAL TRACT*

WILLIAM H. BARNES, M.D.

OAKLAND, CALIF.

THE incidence of primary tuberculosis of the vulva and vagina is rare and yet its importance is none the less significant. Few cases in living subjects have been reported to date. Freidlander reported a case in 1873; six cases have been reported since then. This condition has been much more frequently found at necropsy than in clinical practice and when found is almost always associated with generalized tuberculosis.

The literature dealing with this condition is exceedingly rare, of which Wharton has given us one of the most recent and modern descriptions. A summary of all cases reported would give a series as Wharton says of about 75 cases nearly all of which were discovered at autopsy. Clinicians have failed to discover tuberculosis of the vulva and vagina in the living subject probably because most of the patients had generalized tuberculosis and the vaginal tract was overlooked.

PATHOLOGY

The pathology of this disease is shown by the appearance of one or more chronically inflamed indurated nodules located in the vulva or vaginal wall. They may be separate or conglomerate. Two forms are recognized chronic indolent. The nodule or nodules may be ulcerated and discharging a slight amount of serosanguinous pus. The drainage is usually never excessive. The edges of the ulcers are usually undermined, indurated and irregular with nodular granulating bases which bleed only slightly when manipulated. Frequently the ulcers may have healed, leaving a cicatrix with

a surrounding pigmented area, especially in the involved skin areas, or one edge of the ulcer may have healed and the other edge may show a progressive breaking-down of tissue. Some of the tubercles may show caseation while in other cases caseation is difficult to demonstrate. There nearly always are enlarged inguinal glands in one or both groins. Cases of long duration may show extension of the tubercles into the adjoining tissues involving especially the perineum. Microscopical examination of a biopsy specimen may show little or no direct evidence of tuberculosis only that of a chronic inflammatory area. Several biopsies may be necessary to establish a definite diagnosis of tuberculosis. The blood may present a normal picture, the only exception being that of a low polymorphonuclear giving way to a high mononuclear count. The urine shows no involvement. The freedom of the vaginal tract and vulva from tuberculous infection according to Norris is due to the resistance of the epithelium covering especially the horny layer.

SYMPTOMS

The symptoms may either be local or general depending upon the degree of involvement. The local symptoms are characterized by either no pain at all or a dull ache or slight pain in the region of the vulva or vagina. There may be bleeding and edema of the vulva especially in children. The pain is more severe in the pelvic and lumbar region when there is a pelvic involvement. These patients usually have poor appetites. Intermittent

* Submitted for publication January 6, 1930.

constipation and diarrhea may be complained of where there is an involvement of the intestinal tract. Frequent urination may exist with hematuria where there is an involvement of the urinary tract. Pulmonary involvement is attended with considerable coughing, and occasionally expectoration of bloody sputum, loss of appetite and night sweats. In fact weakness, loss of appetite, and night sweats may be a common complaint among most cases with extensive involvement.

DIAGNOSIS

The patient may be a healthy robust-looking person if the disease has not been one of long standing or she may present an emaciated, weak and anemic appearance. Most tuberculous cases of the vulva and vagina show a pulmonary involvement which first attracts the attention of the diagnostician. Primary cases on the other hand often present greater difficulties in diagnosis because there are no other noticeable foci. Examination for tuberculosis of the vaginal tract is seldom made unless there is a considerable area of infection, ulcerative in character, sufficient to give rise to an unusual vaginal discharge. This condition is quite apt to be overlooked especially in adult women because of the frequency of a leucorrhea which is often given no significance among them. Examination will reveal usually one of two forms, an ulcerative or a hypertrophic type involving the vulva and occasionally the vagina. The ulcerative form is characterized by a solitary or multiple ulcerated nodule located on any part of the vulva and frequently the vaginal walls. There may be a fistula leading from the ulcerated area to a tuberculous focus in the lower intestinal tract or the ulcer may have healed in one area leaving scar tissue behind while it has spread to a new area. The ulcer may be excavated, have sharp undermined margins, or it may be nodular or covered with exuberant granulations which bleed only slightly when manipulated.

The lesion presenting must be differentiated from gonorrhea, senile vaginitis, and an ulcerative condition resulting from trauma, prolapsus, syphilis, cancer, actinomycosis, or esthiomenus. Many cases can be differentiated only by blood tests and histological examinations of biopsies. The histological picture of tuberculous ulcers usually shows areas made up of dilated thrombosed blood vessels, round-cell infiltration and extensive proliferation of epithelioid and connective-tissue cells. These areas or tubercles may show degenerative processes resulting in caseation and giant cells. Giant cells, although usually present, are not however necessary adjuncts to a tuberculous nodule. Special staining may fail to demonstrate *Bacillus tuberculosis* in the nodule.

The hypertrophic form is characterized by an extensive swelling of the labia major or by one or more large rounded indurated nodular areas of the vagina. The areas are covered by thickened epithelium. These cases are much more difficult to diagnose than the ulcerous type and are very frequently mistaken for carcinomata, sarcomata, condylomata acuminata, elephantiasis or esthiomenus. A histological examination is often the only exact method of differentiation and even by this method they frequently offer diagnostic difficulties, for tubercles with giant cells and *B. tuberculosis* are often very difficult to demonstrate. No case should be classified as tuberculous without the characteristic tubercle showing epithelioid cells, dilated blood vessels, giant cells, round-cell infiltration, plasma cells, and if possible *B. tuberculosis*.

The disease is differentiated from a Neisserian infection by failure to find the gonococcus in the stained smears. Gonorrheal vaginitis in children is never ulcerative, tuberculous vaginitis usually is, while chronic non-specific vaginitis shows a tendency for the vaginal walls to adhere to each other resulting in atresia which does not occur in vaginal tuberculosis. Ulcerative conditions of the vulva

and vagina due to trauma or prolapse are always accompanied by a different history than those of other infections and healing readily takes place after the proper correction is made. Lues is often very difficult to differentiate from tuberculosis in these cases. It demands a carefully prepared history and examination including laboratory and serological tests.

The most important problem in diagnosis is the ruling out of malignancy. Carcinoma, in contrast to tuberculosis, is friable, bleeds easily, often grows rapidly, invades the surrounding tissues, metastasizes early to the inguinal glands. A biopsy is many times the only means by which a differentiating diagnosis can be made. Novak feels that a study of the histopathology of the lesion is the only reliable method of diagnosis. Actinomycosis often resembles tuberculosis in its clinical manifestations but the purulent discharge is granular in appearance. These granules when examined microscopically may be readily recognized as actinomycotic fungi bodies. Esthiomenus is characterized by an extensively swollen and discharging ulcer of the vulva. According to Gallagher the etiology is not clear but is generally believed to be that of tertiary lues. No *Spirochaeta pallida* have been found however. It often simulates cancer and lupus.

TREATMENT

The treatment of this serious ailment has almost as many variations as it has observers. No one method of treatment is at all satisfactory for the disease is very difficult to treat with permanent results. Conservative and non-operative methods almost invariably fail as do also the more radical surgical measures. Cullen used radium x-rays with no improvement. Cautery has seldom helped. Excision of the ulcer and of the involved inguinal glands under local anesthesia is usually the method of choice although this procedure has met with many failures. Frequently surgical removal has hastened rather than checked the dissemination

of the disease. Dr. Henry Schmitz recommends the use of ultraviolet rays as a useful adjunct in treatment. Halsted recommends a careful coordination of both medical and surgical aspects in the treatment of this disease.

CASE REPORT

The following case is of considerable interest because of its duration and of the difficulties attending its diagnosis:

Mrs. R. D., housewife, aged forty-four entered the hospital May 18, 1928 complaining of weakness, loss of control of the bowels, and a painless discharging ulcer beside the vulva. The admitting diagnosis was carcinoma of the rectum and vulva with metastases to the liver.

Family History. Father, age and cause of death is unknown. Mother, age unknown, died of stomach trouble. There is one sister alive and well. There is no history of tuberculosis in the family.

Past History. The patient has always been healthy until the present illness. She has never had pneumonia and to her knowledge has never been exposed to tuberculosis. She has not been subject to coughs or sore throats. The menstrual history is insignificant, the periods having been regular up to about one year prior to admission. Since then they have been quite irregular with little or no pain. The last period was about 3 months previous. There have been no miscarriages and no children. The bowels have been regular up until the present illness. There have been no urinary disturbances nor any operations.

Present Illness. The patient states that her present trouble began about three years ago with severe constipation. The condition lasted a few weeks then quite suddenly she noticed that she no longer had control of her bowels for a period of several weeks. Since then there have been alternate periods of constipation and diarrhea, unattended until recently with pain. Recently the uncontrollable bowel movements have been accompanied with considerable bleeding. Her appetite has been quite good although she has lost considerable weight. She has never been jaundiced. There has been no vaginal discharge. Her weakened condition has compelled her to remain in bed for most of the time during the month prior to admission.

PHYSICAL EXAMINATION. The patient is a small emaciated looking white woman of about forty-five years of age. She is sitting up in

are of good quality, rate and rhythm. The blood pressure is 112/68.

Abdomen. The abdomen is scaphoid. There

FIG. 1. X-ray photograph of Mrs. R. D.'s chest. Shows few discreet fairly well-circumscribed areas in both apices. These are probably healed tuberculous areas.

FIG. 2. X-ray of pelvis showing evidence of malignancy. Incidentally it does show comparative size of right and left labia majora. Left side is shown as extremely enlarged.

bed and apparently not in any pain or distress. Her temperature is 99.8°F.; pulse 100; respiration 20. There is a sparse growth of dry hair on her head which is otherwise negative.

Eyes. The movements are normal, there is no nystagmus. The pupils react sluggishly to light and accommodation. The sclera is clear and the conjunctiva pale.

Nose. Negative.

Mouth. The mouth shows many decayed teeth and considerable pyorrhea. The breath is fetid. The mucous membranes are pale, the tongue is coated and the tonsils are small and buried. The posterior pharynx is negative.

Neck. The neck is slender and shows pulsations and no enlarged thyroid. The lymph glands are barely palpable.

Chest. The chest is extremely emaciated but symmetrical. The breasts are atrophied and soft. There are no palpable glands in the axillae. There is good expansion of the lungs with equal displacement at the bases. The lungs are resonant throughout, there are no râles.

Heart. The heart is normal in size, the P.M.T. well within the nipple line. The sounds

are no masses felt, no tenderness and no rigidity. The liver, spleen and kidneys are not palpable. There are indurated but not tender glands the size of an almond in each inguinal region.

Rectum and Genitalia. There is pus exuding from the rectum. There is loss of sphincter tone. About 1 in. up from the anal orifice there is an annular mass constricting the rectum. It is firm, nodular, has little tenderness and shows little tendency to infiltrate into the surrounding tissues. There is a nodular mass involving the left vulva and perineum. The ulcer has a granulating base and shows little tendency to bleed. The edges are irregular and somewhat excavated.

Extremities. The extremities are normal in appearance except for emaciation. The reflexes are normal to hyperactive.

LABORATORY REPORTS. *Urine.* Non-catheterized specimen. Amber. Sp. Gr. 1.012. Reaction, neutral. Albumin, negative. Sugar negative. Microscopical, white blood cells, many red blood cells. Six to 8 high power, many bacteria, many epithelial cells, few hyaline and granular casts.

Blood Count. Hb. 55 per cent Dare. R.B.C. 4,620,000. W.B.C. 5050: polymorphonuclears

60 per cent, small monocytes 22 per cent, large monocytes 13 per cent, eosinophiles 3 per cent, basophiles 2 per cent.

deeper tissues are infiltrated with leucocytes both polymorphonuclear and mononuclear together with a number of plasma cells. The

FIG. 3. Photomicrograph of section of tissue taken from hypertrophic area of labia majora. Magnification $\times 150$. Section shows papillary hypertrophy of cutis and widening of lymph spaces with areas of round-cell infiltration.

FIG. 4. Magnification $\times 450$. Area shows ulcerated surface with walls edematous, widened lymph spaces, round-cell infiltration, plasma cells and some hemorrhagic infiltration. There is considerable proliferation of epithelioid cells.

Wassermann. May 24, 1928 negative. June 18, 1928 negative. June 25, 1928 negative. July 7, 1928 negative. The last three tests were made following provocative treatments.

X-ray. Posterior-anterior x-ray of the chest May 28 and June 30 showed areas of increased density in the apices of both lungs. The areas had the appearance of old healed scars. (See Fig. 1.) X-ray of pelvis showed no malignancy of the bony pelvis (Fig. 2).

Microscopic Smears and Biopsies. May 28, 1928. Microscopic smears from the ulcer and pus from the rectum were negative for *B. tuberculosis*. The interne reported insufficient pus for guinea-pig inoculation. Pus showed no intracellular gram negative diplococci nor actinomycotic granules.

May 28, 1928. Specimen taken from the left labia and edge of the ulcer. Report shows section of skin and subcutaneous tissue. The

lesion is an inflammatory one without evidence of malignancy. (See microphotograph, Fig. 3.)

June 6, 1928. A biopsy specimen from another hypertrophic area shows extensive round-cell infiltration and has no tendency to vascular grouping. Diagnosis: chronic ulcerative inflammation. (See Fig. 4.)

June 28, 1928. Biopsy of a left inguinal gland shows numerous microscopical areas of caseation with accumulations of lymphocytes, epithelioid cells and many typical giant cells. Diagnosis: tuberculous lymphadenitis. (See Fig. 5.)

June 29, 1928. Spinal puncture showed spinal fluid clear with a cell count of 4 per cubic millimeter.

July 17, 1928. A guinea pig was inoculated with pus from the ulcer. Report of August 27, 1928: guinea pig positive for tuberculosis.

DIAGNOSIS. An exact and immediate diagnosis was difficult in this case because of its

similarity to several other diseases. The following impressions and consultant opinions were made:

May 22, 1928: (1) Tuberculosis vulva, perineum, and rectum.

(2) Syphilis, tertiary stage.

(3) Carcinoma.

(4) Actinomycosis.

Surgical and dermatological conferences were asked for.

Surgical. May 23, 1928: Appears like tuberculosis or carcinoma. June 1, 1928: History suggestive of malignancy but rectal mass has not the consistency of a malignant mass. Laboratory diagnosis necessary.

June 28, 1928: This condition is syphilitic and advise antisiphilitic treatment and biopsy of inguinal gland.

Dermatological Impressions.

June 1, 1928: 1. Carcinoma.

2. Syphilis.

3. Tuberculosis.

4. Granuloma annulare.

Requested smears for tuberculosis and Donovan bodies, also therapeutic test for syphilis.

Final Diagnosis.

July 6, 1928: Ulcerative and hypertrophic tuberculosis of vulva and perineum, determined by examination of pathological specimens obtained from a series of biopsies.

PROGNOSIS. The prognosis of the patient is very grave because of the poor appetite, the progressive emaciation and weakness and the increase in size of the involved area. The long duration of the disease with the progressive loss of weight and strength has left the woman in a very serious condition and there is apparently no resistance left for fighting the infection.

TREATMENT. Surgery is certainly contraindicated, thus leaving medical care the only alternative. Symptomatic and hygienic treatment were given such as rest in bed, sunshine and plenty of fresh air. Cleansing douches of potassium permanganate 1:1000 solution were used on the ulcer. Codeine and luminal were administered for pain and restlessness as was deemed necessary. Seven doses of neoarsphenamine, ranging from 0.3 to 0.6 gm., a total of 3 gm., distributed over a period of one and one-half months were administered intravenously. This was ordered by the dermatologist first for diagnostic and later for therapeutic reasons. It was considered that the patient

showed some improvement and the neoarsphenamine was thereby indicated.

CLINICAL COURSE. Mrs. D. was sent to

FIG. 5. Microphotograph of inguinal lymph gland. Case of Mrs. R. D. Magnification $\times 80$. Section shows considerable proliferation of epithelioid tissue with good number of giant cells.

the hospital May 18, 1928 because of her failing health and ulcerous condition of the vulva. After entering the hospital her condition continued on a downward course. It was thought for a time that there was a slight improvement due to the neoarsphenamine injections, but the response was only very slight and temporary. July 7, 1928 she became delirious but this condition cleared up within twenty-four hours. Her weakness and anemia progressed. Her temperature ranged from 97° to 102° F. Food could not be retained and she passed away in coma August 1, 1928.

AUTOPSY REPORT. The body is that of an emaciated white woman about forty-five years of age. There are no scars on the head, chest nor abdomen. The extremities are negative. There is a discharging, ulcerated, and indurated mass involving both labia majora and minora and extending bilaterally to both sides of the sphincter ani. This mass extends laterally

about 5 cm. over the right buttocks, it also surrounds the meatus but does not involve the mons veneris. The brain shows a slight edema. The cerebral spinal fluid is cloudy but no B. tuberculosis are demonstrable. There are no hemorrhagic areas.

The thoracic and abdominal contents were exposed through the usual midline incision. There is no excess of fluid in either body cavity. There are fibrous adhesions of the apices of both lungs to the thoracic wall. Macroscopic sections of the lungs revealed healed fibrous and calcareous areas but no active tuberculous areas. Microscopically the areas showed active tuberculous proliferation. The heart is normal in size with no lesions manifested.

There is no evidence of infection or malignancy in the viscera of the abdominal cavity. The liver shows some fibrosis and fatty degeneration. The spleen and kidneys are apparently normal in size showing no areas of infection. There is a stricture of the rectum about 7 cm. from the anus. There are enlarged nodular epiploicae continuing to within 20 cm. of the ileocecal valve.

Diagnosis. 1. Possible beginning tuberculous meningitis.

2. Tuberculous vulvitis with extension to the inguinal lymph nodes and rectum.

3. Macroscopically the lungs showed apparently healed tuberculosis of both apices. Microscopic examination showed active tuberculosis of these areas.

4. Fibrosis of liver with fatty degeneration.

COMMENT

This case bears out the findings previously described by others and referred to in this paper, namely prolonged duration of illness, progressive emaciation and

weakness, and manifesting difficulties in diagnosis and treatment. A wider study of the case discloses a discrepancy in diagnosis and one for which we should criticize ourselves, and that is the omission of an early guinea-pig inoculation test. No doubt the time for arriving at a diagnosis could have been shortened by at least six weeks by this procedure. However, the fact still remains that clinical and pathological diagnosis of tuberculosis of the vulva may require considerable time and repeated biopsies.

CONCLUSIONS

1. Primary tuberculosis of the vaginal tract is rare, due to the resistant qualities of the epithelial covering.

2. Differential diagnosis of tuberculous vulvitis and vaginitis requires careful observation and may also require many laboratory tests, including biopsies and guinea-pig inoculation.

3. Most cases of tuberculosis of the vaginal tract are complicated by tuberculous foci of infection in other parts of the body.

4. The prognosis of tuberculosis of the vaginal tract is exceedingly grave.

5. Treatment to date has been very unsatisfactory. It must of necessity include the best of medical care in addition to rest, air, food and sunshine. Surgery may be a useful adjunct providing the focus of infection is localized to a small area and the patient's health is not too severely depleted. Surgery has no advantages in disseminated cases. Cautery should be considered in small areas of accessible foci.

MEDIASTINITIS FOLLOWING REMOVAL OF THYROID*

FRANCIS S. MAINZER, M.D.

CLEARFIELD, PA.

MEDIASTINITIS is not infrequent, but is as a rule not recognized as such, which is probably due to the fact that it arises as a complication of some process elsewhere whose symptoms mask those of this condition itself.

The mediastinum is a closed space, therefore is a difficult space to drain either by nature or by operative means so that extension of inflammation to vital structures is apt to take place.

In inflammations of the neck, in which group this case report belongs, mediastinitis is rare (that is, if the inflammation arises in the superficial tissue) as the downward path is well guarded by fascia, whereas in the deeper regions, especially along the larynx, trachea and esophagus, extension is easier, but this being the case the inflammation must extend to the deep cervical fascia from whence it passes into the mediastinum.

An exhaustive search of the literature has not disclosed a similar case on record; therefore the following case history is submitted:

H. A., female, aged 56, was first admitted to the hospital November 2, 1927, complaining of a large hard mass in the neck, loss of weight, weakness, choking sensation and shortness of breath. The history was that she had had a hard mass in the neck for seven years, but during the past three months it had become markedly larger. The choking sensations and shortness of breath had only been noted for about 4 months. She stated that she had lost about 45 lb. in a year.

Physical examination revealed a fairly well nourished female, bronzed and rather toxic. Neck: A large mass was present in midline, extending laterally (bilateral), which moved with deglutition; mass was nodular and extremely hard, appeared rather fixed. Heart: Both sounds were present over the apex and

aortic region, rate was fair, fibrillation and a systolic murmur were present. The hemoglobin was 80 per cent, erythrocytes numbered 4,050,000, leucocytes 9000, polymorphonuclear leucocytes 73, lymphocytes 23, large lymphocytes 4 per cent. The urea-nitrogen was 19.62 mg., creatinin 1.2 mg., sugar 88 mg. The Kahn test was negative. The basal metabolism reading was plus 1. Urine: specific gravity 1.020, acid reaction, light cloud of albumin, occasional leucocytes, hyaline casts. A diagnosis of carcinoma of the thyroid was made.

The patient was placed on the routine preliminary treatment and five days later maximal subtotal thyroidectomy, consisting of excision of isthmus and both sides, was done by Dr. S. J. Waterworth. Tracheotomy was also done following removal.

Operative Record. The carcinomatous mass, very large and extremely hard, had pushed the trachea to the left in the form of the letter J. The carcinomatous mass was attached to the common carotid sheath. In following the carcinoma over the isthmus it was found that the anterior wall of the trachea had been invaded and a tracheotomy was done, a long Jackson tracheotomy tube being used. As nearly as possible all vestige of carcinomatous tissue was removed except that of the anterior wall of the trachea. In order to remove this, it would have been necessary to remove the anterior half of the trachea over a distance of about 3 in. of its length.

Pathological Report. Specimen of complete thyroid, measuring $3 \times 7 \times 4$ cm., $7 \times 6 \times 4$ cm., $5 \times 4 \times 3$ cm. and five other smaller pieces. The cut surface was yellowish white, hard, rather uniform with a few hemorrhagic areas. All tissues showed similar gross appearance, except one small nodule that appeared to be more colloidal.

Microscopic Report. Section consists of almost solid masses of large cells like thyroid, but are large. Some contain vacuoles of colloid material. There is a lobulated arrangement of the cells.

Diagnosis: Carcinoma of the thyroid.

Following the operation she had a moderate

* From the Department of Surgery, Clinic of Dr. S. J. Waterworth, Clearfield, Pa.
Submitted for publication September 30, 1929.

postoperative reaction, temperature never reaching above 103.2°F. (rectal) and was within normal limits in about 8 days. The tracheotomy

FIG. 1.

tube was changed several hours each day. Three days later it was left out entirely and the wound was allowed to heal. On the twenty-eighth day following admission the patient was discharged with thyroidectomy wound almost closed. Her general health had improved. She was advised to return every month for a check-up examination on her condition.

She returned several times, after which she was not seen until a year had passed. She was then admitted to the hospital for the second time, with a history of having lost weight for eight months. She had considerable irritation in the neck with choking which made it impossible for her to sleep. At this admission the patient was emaciated, bronze colored and felt very much depressed. Examination of neck revealed a hard mass on the left side of the trachea. Two days later an operation was done¹ with the following report: excision of all carcinomatous tissue which, on the left, extended behind the trachea involving the esophagus. A small area of the esophagus was caught with the artery forceps in dissecting, but apparently was not punctured. The area was turned in with catgut sutures. Dissection was very difficult and was attended with great anterior hemorrhagic oozing which was controlled with

¹By Dr. S. J. Waterworth

cautery, suture and packing. In dissecting off the carcinomatous mass of the trachea, the anterior portion of trachea, the second and third tracheal rings had been absorbed, carcinomatous tissue growing within the lumen of the trachea. A long tracheotomy tube was introduced and the wound was packed with acriflavine gauze, skin flaps partially closed over gauze.

Pathological Report. Carcinoma of thyroid (recurrent).

Following this operation she had a moderate postoperative reaction. The temperature reached 103.4°F. (rectal) and on the third day began coming down. The tube was changed daily and considerable mucus was present, hence a catheter was placed through the tube, which was in turn connected to an aspirating apparatus. About every two hours aspiration was carried out. The wound was kept antiseptized as best as it could be, but due to mucous coming in contact with it a slight infection occurred and immediately the temperature jumped several degrees. In two days it was noted that a small opening was present which extended downward into the mediastinum. A catheter was placed in the sinus tract and a quantity of pus aspirated. This was carried out several times a day. The temperature during this time ranged between 100.4 and 105.2°F. (rectal). The third day following aspiration of pus, Dakin's solution was used for irrigation. This treatment caused the fever to drop several degrees. Two days later she began having severe pain in the chest with shortness of breath. This was followed by a rise in temperature to 106°F. (rectal) which fell to normal the next morning. That afternoon sodium iodide was passed through the catheter within the sinus tract and a roentgenogram was made,² following which fluid was again aspirated. After this procedure the patient rested well until several hours later when she began complaining of severe pain in the chest which radiated to the suprasternal notch. The pain lasted for about two minutes, then suddenly she ceased to breathe. Artificial respiration was resorted to but without avail. No autopsy could be obtained, but the roentgenogram will prove the diagnosis.

²By Dr. W. E. Reiley.

FOREIGN BODIES IN THE BRAIN*

LEO DRETZKA, M.D., F.A.C.S.

DETROIT, MICH.

ALTHOUGH brain surgery, we learn from archeologists, is as old as any branch of the science, it is only since the development of the roentgen-ray and the fluoroscope that the surgeon has been equipped to invade with any degree of certainty the innermost domain of personality and of life itself. The experience gained in the World War, when a vast amount of radical brain surgery was performed, has greatly enhanced our knowledge of what can be done within the cranial vault. It has given the surgeon a new boldness for emergencies, it has drawn with greater precision the line beyond which we may not venture.

Our great cities send to the operating tables a stream of casualties not unlike those moving back from a relatively quiet sector during the war. The injuries of industry, of traffic, and of crime all include a high percentage of cases in which penetration of the brain by foreign bodies is to be suspected.

Any injury to the head suggests the possibility of a foreign body in the brain. Not infrequently an uneventful recovery from a seemingly trivial head injury is followed in after years by brain abscess, migraine, vertigo, mental confusion, epilepsy, extreme lassitude and other symptoms originating in mechanical interference with the functioning of various parts of the brain.

These notes are based on a personal study of 2308 head injuries admitted to the Receiving Hospital of the City of Detroit during a four-year period. Of this number, 1662 were fractures and 62 were wounds caused by missiles or weapons.

It is imperative in every case of brain injury to proceed as rapidly as possible with a complete fluoroscopic and roentgen-ray examination, made with exacting

care by a trained expert. If the case presents itself at any distance from the facilities for such examination, it should be transported to the proper place as soon as shock has been overcome sufficiently to make such a move safe. Next in importance, and never to be neglected, is a neurological examination, conducted by a specialist in that field.

Before entering upon a discussion of certain types of brain injuries in which foreign bodies are involved, it is well to meet fairly the question as to just what conditions indicate the necessity of operation. It is true that very often foreign bodies may become encapsulated and cause no radical symptoms immediately. It is, therefore, natural for the surgeon whose practice does not include a large number of brain traumata to follow the course that seems safest at the time. This is probably a logical decision if there are not available the very best aids, both human and mechanical, to insure the success of an entrance into the deep tissues of the brain. But where such aids are available, it is best to clear away at once the possible causes of accumulative complications which may lead to the gravest consequences.

In examination of brain injuries involving foreign bodies, it should be borne in mind that seldom is there a single well-outlined object to be sought. Penetration of the hair layer, of skin and bone and sometimes of some form of headgear, is likely to carry with it skull splinters and fragments of the missile itself, together with a trail of other material potentially infective.

THROUGH-AND-THROUGH WOUNDS OF THE CRANIUM

Systemic shock is, of course, terrific

* Submitted for publication September 10, 1929.

in a through-and-through penetration and urgent attention to general resistance is of first importance. The wounds of entrance

FIG 1 W. L., F. 987, aged forty. Kicked and stabbed. Roentgen-ray shows $\frac{1}{2}$ in. point of knife blade embedded in median line of frontal bone with linear fracture 1 in. in length about 4 in. above glabella. Recovery. Knife blade removed by operation

FIG. 2 Shows knife blade illustrated in Figure 1. Viewed in this position, it may be interpreted as foreign body in brain and not embedded in skull bone.

and exit are shaved and thoroughly cleansed, and asepsis maintained, without any effort either to install drainage or to close the wounds. As soon as it is practicable, roentgen-ray examination should

be made to determine whether any foreign matter has lodged in the pathway of the wound. If the examination is negative, the wound of entrance should be excised sufficiently to assure the removal of infected and damaged soft tissue. Then the bony opening must be enlarged to expose healthy dura. The ragged edge of the dural wound is also trimmed away and the cortical lesion treated as indicated in the individual case. This will also assure natural drainage. It is not necessary to excise the wound of exit.

FOREIGN BODIES IN THE BRAIN

A foreign body, or a group of them, having been located within the brain and the advisability of removal determined upon, preparations for the operation should include the fluoroscope and electro-magnet, both of which are to be in readiness for instant use. It should be borne in mind that while the lead cores of modern

FIG 3 E. S., F. 5851, aged thirty-three. Shot in quarrel. Roentgen-ray shows fracture of left temporal bone. There is also evidence of gunshot fracture of left orbit. Numerous metallic fragments embedded in outer margin of orbit. One large fragment appears to be partially in left sphenoidal sinus. Discharged, recovered, ten days later. No symptoms.

bullets will not respond to the magnetic pull, the alloy jackets, which often are stripped from the core and left in the

wound, frequently behind the bullet, sometimes beyond it, or flung off at angles to its course, are attracted by the magnet.

COMPLICATIONS

It is to avert complications that the radical procedure of removal of all foreign

FIG. 4. J. P., F. 4586, aged twenty-eight. Shot trying to stop fight. Roentgen-ray shows opaque shadow, shape of bullet, which is just above right mastoid within skull. Discharged, recovered, sixteen days later. No symptoms. No operation.

FIG. 5. Bullet which lies posterior to right ethmoidal cells. Large fragment to right margin of orbital ridge. Also minute fragments within region of right orbit.

The majority of foreign bodies are, however, removed by direct operation. If the wound of entrance is to serve as the path through which the foreign body is to be extracted, then the surgeon must enter it with care, giving all his attention to the aseptic cleansing of the tract of foreign material.

Local anesthesia is invariably preferable. It enables the surgeon to work without the interference of the mask, and does not tend to upset the balance of vitality, which may be very delicate in any case of gross injury to the brain.

Hemorrhage. It is frequently imperative that immediate attention be given to the control of severed blood vessels or sinuses and that the removal of the missile be delayed until some more opportune time. A bullet or fragment of bone may penetrate the sinuses, most frequently the longitudinal on account of its exposed position. Hemorrhage from the middle meningeal arteries must be immediately controlled by ligature. Frequently, however, the missile or bone fragment lies in the direct field of operation and is readily removable.

objects is advised. The most scrupulous adherence to surgical asepsis is, obviously, required, with meningitis as a routine outcome of infection.

FIG. 6. Bullet in lateral aspect of right orbit which has fractured lateral orbital rim.

Drainage. There is no hard and fast rule regarding drainage. When it has been possible to remove foreign material, and pulped brain tissue, and the oozing has ceased, then a rubber wick at the extreme angle of the wound is usually sufficient.

In the presence of pus deeper drainage is necessary. Hard rubber tubes must never be employed. Drainage is to be continued

in the absence of focal symptoms, it is difficult to make a definite diagnosis. After the abatement of the acute symp-

FIG. 7. Bullet $1\frac{1}{2}$ in. to left of median line and $\frac{1}{2}$ in. above line drawn between auditory canals. It is $\frac{1}{2}$ in. posterior to clinoid process.

until all oozing has ceased or bacterial examination warrants that it be discontinued. Irrigation of the wound with warm saline often facilitates drainage.

Abscess is usually a rather late consequence of a foreign body within the brain. Although it is usually averted by the complete removal of the foreign matter, there is always the likelihood that it will occur even after that has been accomplished. Headaches, repeated rises in temperature, mental dullness, point to the possibility of abscess.

About 15 per cent of brain abscesses are traumatic. The usual causes are fractures of the vault infected from without, or a foreign body penetrating through an infected sinus. A traumatic abscess is usually in the direct line of the original injury. It may be free or it may be encapsulated and it is usually single. When in the motor cortex, it often induces epilepsy.

I find it convenient in classifying symptoms, to divide them into acute, dormant and exacerbating types. The acute type has an almost immediate progressive onset: the fever is high and accompanied by delirium, anorexia and vomiting. This type resembles a purulent meningitis, and

FIG. 8. A. P., F. 1500, aged thirty-three. Complaint was headache back of left ear and periodical attacks of blindness. Was shot in hold-up three years previous and after being confined to hospital for twenty-one days was discharged. Since then has become progressively worse.

Roentgen ray shows oblong opaque shadow within cranial cavity on left side on line with upper border of mastoid. Also small opaque shadow embedded in soft tissue.

Operation: Local anesthetic 1 per cent novocaine. Debridement was done at site of entrance. Skull was thickened at place of entrance. Dura was incised and bullet found lodged $\frac{3}{4}$ in. beyond cortex. It was completely encapsulated.

Discharged recovered, without symptoms, twelve days after operation.

toms, drowsiness, stupor and coma set in. The pupil on the side of the abscess may be dilated and fixed.

In the dormant type, an abscess may remain dormant for years and produce only such vague symptoms as headache, mental dullness and impairment of vision, as witness Case 1:

CASE 1. J. B., a southern negro, who had passed the draft board and was in an embarkation camp ready for overseas duty. The strenuous drilling caused him to complain of severe headaches and he was removed to the base hospital for observation. Several days after admission, he began having convulsions which increased in severity. His neurological examina-

tion was quite negative, as was his history. A roentgen-ray examination of the skull disclosed a knife blade $1\frac{1}{2}$ inches in length

toms of the acute type. These symptoms are followed by convulsions, aphasia, monoplegia or hemiplegia. The localizing

FIG. 9. Bullet in lateral aspect of right orbit which has fractured lateral orbital rim.

penetrating the occipital bone and extending into the brain. More careful questioning helped him to recall a fight about ten years previous to this time, in which knives were used as weapons, but there was no disability at the time and he had engaged in his regular employment all these years without the least discomfort or the knowledge of the knife blade in his brain.

Operation for brain abscess and removal of knife blade; left occipital region. A large encapsulated abscess was evacuated. The walls of the abscess were extremely thick and the cortex destroyed. Irrigations but no drains were used. Exposure of the cavity was done by removing a large area of bone overlying the abscess. No brain hernia resulted. Complete recovery.

It is this type which is so frequently found at autopsy.

A history of previous injury usually accompanies the exacerbating type. The patient has apparently recovered from a skull injury when suddenly a high fever and leucocytosis sets in with all the symp-

FIG. 10. Knife blade removed from brain. It was surrounded by cortical abscess. Recovery.

ptoms, either spasmodic or paralytic, indicate the center which is irritated and destroyed, as witness Case II:

CASE II. I. L., admitted to the hospital Sept. 19, 1924, following, an automobile accident. He was semiconscious and restless. There was an abrasion and contusion of the left face and scalp, and a slowly oozing hemorrhage from the nose and mouth. His lower jaw was fractured. The pupils were unequal, the left being larger than the right. Roentgen-ray examination of the skull was negative.

September 24. Entirely unconscious and delirious with no paralysis.

October 2. Condition improving. There was a return to consciousness, but a typically septic temperature. At this time, a purulent discharge of the left ear evidenced itself, which the aurist pronounced an otitis media.

Neurological examination disclosed a partial paralysis of the right arm and leg and left facial paralysis. Reflexes extremely active.

Diagnosis. Abscess of the brain, left temporosphenoidal region.

Operation. An elliptical incision was made and the skull exposed. A comminuted fracture of the petrous portion of the temporal bone was exposed. The loose fragment was removed and the defect enlarged. The dura was tense and there was no pulsation. Immediately on

incising the dura, the brain bulged into the wound. Thick staphylococcic and streptococcic pus escaped after the cortex was punctured. The opening was enlarged and a cavity the size of a hen's egg exposed. The patient made an uneventful recovery. There was no brain hernia.

An examination of the eye grounds often shows a retinitis due either to pressure or to toxemia.

Abscesses develop more frequently in the white matter of the brain because this is less resistant and liquefies more easily than the cortex upon which the pus accumulation impinges.

Recent abscesses contain colored pus and later this pus becomes greenish. Staphylococci and streptococci are the organisms most frequently found in traumatic cases.

Epilepsy sometimes occurs as a sequel of penetration of the brain by a foreign body. Site of the injury seems to have no special bearing on the occurrence of this condition, nor have we any adequate amount of material on which to base conclusions regarding preventive measures. The follow-up of brain injury cases, occurring as they do in the big industrial centers for the most part, is unsatisfactory.

Check on patients seemingly recovered is impossible. We, are however, justified in assuming that prompt and effective removal of all foreign bodies from the brain vault is a precaution materially tending to decrease the likelihood of the epileptic complication.

MORTALITY

High mortality in injuries of the brain itself must be expected. This is an argument for, rather than against, the courageous attempt to avert disaster in the event the patient is destined to survive. Of course, there are brain areas whose penetration must result fatally.

POSTOPERATIVE CARE

After operation the patient should be propped up in bed and the head covered with ice bags. Morphine should be given every five hours for several doses to insure rest and quiet. Bromides may be used during convalescence if indicated. The possibility of infection is the most serious complication which the surgeon must look for: a rise in temperature, delirium, vomiting, muscular twitching or neck rigidity indicates its onset.

UTERINE POLYPOSIS

MALIGNANT TRANSFORMATION WITH PULMONARY METASTASES*

WALTER T. DANNREUTHER, M.D., F.A.C.S.

NEW YORK

THE several histologic varieties of cancer of the uterine corpus, with the exception of chorionepithelioma, are characterized by relatively slow destruction of the myometrium, late perimetritic lymphogenous metastases (as contrasted with rapid parametrial involvement in cases of cancer of the cervix), and abnormal bleeding or a thin leucor-

rhea as the earliest symptom. In the beginning of its progress, it can only be detected by microscopic examination of endometrial curettings. Hence, early diagnosis is predicated upon a diagnostic curettage, and a favorable prognosis is in turn dependent upon prompt recognition of the disease with immediate surgical intervention.

* From the Department of Gynecology, New York Post-Graduate Medical School and Hospital. Read before the Section on Obstetrics and Gynecology, New York Academy of Medicine, May 28, 1929.

Although malignant polyps are said to develop from distended endometrial glands, the literature is not enlightening

the myometrium; (6) the tendency of corporeal cancer to metastasize to remote organs through the blood vessels instead

FIG. 1. Papillary projections of polyp protruding from cervix. Many layers of foamy polygonal cells with small dark nuclei are arranged around a thin central vessel.

concerning the tendency of benign glandular polyps of the fundus to undergo malignant transformation. The appended case report together with the histopathology of the specimen, exemplifies the following important points: (1) the metaplastic transition of a benign lesion of the endometrium into a malignant growth; (2) the inclination of some practitioners to perform a therapeutic rather than a diagnostic curettage for abnormal uterine bleeding; (3) the wisdom of removing the uterus for extensive uterine polyposis; (4) the long period of time that may elapse between the initiation of malignant disease of the uterine fundus and widespread destruction of the myometrium; (5) the pronounced proliferation of some papillary adenocarcinomatous growths, with comparatively slight infiltration of

FIG. 2. Uterus opened, showing huge polypoid mass of friable adenocarcinomatous tissue.

of through the lymphatics, probably because after the climacteric the lymph channels become small and their circulation inactive; and (7) the impotence of the pelvic surgeon to save life when such metastases are already present.

FIG. 3. Bulk of adenocarcinomatous mass has been elevated, to demonstrate cornual attachments, remarkable normality of most of myometrium, and extensive endometrial polyposis, many areas of which are still benign in character.

CASE REPORT

Mrs. E. B., aged sixty-three residing out of the city, with an irrelevant family and previous personal history, was referred by her physician on March 19, 1928. She had menstruated at fourteen, married at seventeen,

had one normal labor in her early twenties, and passed through an uneventful menopause at forty-nine. Pelvic symptoms appeared for

FIG. 4. Infiltration of endometrium with tremendous number of plasma cells. Endometrial lining is metaplastic cuboidal epithelium. There are irregular groups of "benign" glands, also with metaplastic epithelium.

the first time three years previously, when she noticed a little watery vaginal discharge, spotty bleeding, and occasional shreds of tissue. During this three-year period she was curetted twice by two different physicians, but neither one saved or examined the curettings.

The patient was a well-nourished, robust, elderly woman. There was no evidence of anemia or cachexia. Pulse 72, blood pressure 132/82, blood count and blood chemistry normal. Thyroid normal, heart sounds good, lungs clear, and abdominal examination negative. There was a moderate degree of cystocele and rectocele. A pedunculated mass with a necrotic surface, about the size of a walnut, projected from the cervix. The uterus was symmetrically enlarged but did not feel unusually hard. The adnexa were normal.

The patient deferred entering the hospital for removal of the cervical polyp (which was presumed to be malignant), diagnostic curettage, and radium therapy, until April 10.

The laboratory diagnosis, made on the specimens submitted at that time, was papillary adenocarcinoma and chronic endometritis (Fig. 1). The report further stated: "the tissue is very necrotic and shows marked evidence of dissolution, surrounded by extensive necrosis and hemorrhage. Sections from the curettings show narrow glands, with normal epithelium, surrounded with lymphocytic infiltration, which is scattered in the dense stroma."

Preoperative Histopathologic Diagnosis. Chronic endometritis, polyposis and papillary adenocarcinoma.

Operation. The patient delayed re-entering the hospital until May 7, when a wide pan-hysterectomy was performed. Her convalescence was uneventful and she left the hospital on the fifteenth day.

Pathological Report. Uterus weighs 175 gm. It measures 14 cm. in length and 10 cm. in width. It is uniformly enlarged. The cervix has a normal vaginal collar of mucosa. Both tubes and ovaries are attached. Each tube is 11 cm. long and has a free fimbriated end. The tubal serosa is congested and covered with small cyst-like growths, varying from 2 to 4 mm. in diameter. The tubal lumen is narrow and seems to be free. Both ovaries are similar, measuring 4 cm. in diameter, and are covered with normal whitish serosa. On section, diffuse fibrosis is seen, with some yellow remnants of corpus luteum.

On opening the uterus, the cavity is found filled with polypoid masses of friable tissue (Fig. 2). They break down easily. Some of them hang down from the fundus into the cervical canal. Filiform projections are distinct in some; in others there is much necrosis. Two larger masses are seen in each cornu, and these seem to be connected by chain-like extensions. The endometrium is cushion-like everywhere. There are numerous polypoid masses, and some of them have stems (Fig. 3). The polyps vary from 3 to 15 mm. in diameter. At the base of the tumor irregular extension of the growth is noted, but this does not penetrate more than 3 or 4 mm., and the growth is surrounded by at least 2 cm. of fibromuscular uterine wall, which is firm in consistency.

Sections show irregular islands of endometrium. In some places there is very rich inflammatory infiltration all along the surface of the endometrium, which seems to consist almost entirely of plasma cells (Fig. 4). The covering consists of metaplastic epithelium of rather low

cuboidal cells. In some places there are endometrial glands which are lined by one or more layers of cylindrical cells. There are no mitotic

serous cells. They contain homogeneous pink-staining substance.

Pathological Diagnosis. Chronic endome-

FIG. 5. Border of benign polypoid hyperplasia of glands and endometritis.

FIG. 6. Border of malignant polypoid growth of fundus, derived from metaplastic epithelium. Atypical adenocarcinoma of uterus.

figures in these areas, although the cells are irregular in shape and surrounded by typical stroma. Many areas show superficial erosions.

Sections of some polyps show hyperplastic glands with hemorrhagic stroma. These glands are surrounded with rich inflammatory infiltration of lymphocytes and plasma cells. No epithelial invasion is evident (Fig. 5).

In other sections, the base of the growth is seen, with atypical cells predominating. These cells are large and pale, and have small dark nuclei. A few mitotic figures are seen. The surface of these polyp-like outgrowths shows fine papillary projections, with stems of stroma in which there are many layers of similar large pale cells (Fig. 6).

Sections of the ovary show marked fibrosis and old hyalinized follicles. There is no evidence of metastatic growth.

Sections of the tubes show somewhat thickened folds with diffuse fibrosis. The blood vessels are congested and distended. The nodules on the serosa, seen in the gross, correspond to small cysts which are lined with flat

tritis with activity. Benign uterine polyposis. Papillary adenocarcinoma of the fundus uteri. Peritoneal cysts of the fallopian tubes.

Pathological Note. This growth is of the differentiated type and is probably of long duration. There is a very extensive diffuse endometritis of an almost pure plasma cell type, and there are multiple foci of glandular hyperplasia, which in some places form benign, and in others distinctly malignant, proliferation.

Follow-up. The patient reported on October 6, 1928, free from pelvic symptoms and apparently in excellent general condition. There was no evidence of local recurrence. The patient stated, however, that she had noticed occasional attacks of vertigo. Since she had not lost weight, and her pulse rate, blood pressure, and urine were normal, she was advised to return to her physician. A few days thereafter she developed an irritating cough, which could not be accounted for and which failed to respond to the usual remedial measures. An x-ray examination of the chest was therefore deemed advisable.

X-ray Examination of the Chest. Ventro-dorsal, dorsoventral, and right lateral views. Roentgenographic and fluoroscopic study.

FIG. 7. X-ray picture of chest, six months after hysterectomy. Adenocarcinomatous metastases in lung tissue are seen distinctly.

The chest is symmetrical. Right hilum moderately enlarged and thickened. A circular shadow of increased density is seen on the right side, having a diameter of $1\frac{3}{4}$ inches. This involves the lung parenchyma, mesial first and second zones, slightly above the hilum (Fig. 7). Another circular shadow, much smaller and less dense, is seen on the left side in the infraclavicular region. There is a moderate amount of peritruncal thickening of the right and left descending bronchi. The heart is slightly enlarged to the left. Aortic arch not widened. Retrocardiac space is clear.

X-ray Diagnosis. Metastatic carcinoma of the lung.

Progress. The patient was sent to Florida for the winter. Her condition apparently

remained the same for a few weeks, but then became slowly worse, and she returned home on March 31, 1929. Another roentgenographic examination of the chest on April 2 showed various sized nodules throughout both lungs, characteristic of metastatic malignancy. The patient was drowsy much of the time, irrational occasionally, and extremely weak and emaciated. She coughed a great deal but did not suffer from pain. Death occurred on May 21, 1929, and an autopsy was refused.

COMMENT

The histogenesis of this adenocarcinoma of the uterus can be traced by the discovery of different areas in the extirpated specimen which still exhibit the several stages in the transformation of a benign process into one that is malignant. It seems logical to assume that the sequence of events consisted of: (1) severe inflammatory edometrial changes, (2) reparation, (3) overgrowth of glandular tissue, (4) polypoid formation, (5) malignant alterations in the surface epithelium, and (6) the development of papillary adenocarcinoma.

A correct diagnosis soon after the onset of symptoms by either of the gentlemen who curetted the patient, followed by immediate hysterectomy, might have anticipated the malignant process entirely, and thus precluded the remote metastases which rendered the delayed operation futile and caused the patient's death. The postoperative clinical history suggests the likelihood of cerebral as well as pulmonary involvement, and both of these were probably present when the patient finally came to operation. It is unfortunate that an autopsy was not permitted.

RECTAL ADENOMATOUS POLYP

WITH CARCINOMATOUS DEGENERATION*

DANIEL H. BESSESEN, M.D.

MINNEAPOLIS, MINN.

A MARRIED woman, forty-nine years of age, complained of bleeding from the rectum for three or four months. Her husband and 3 children were well and there were no leading points with reference to her present illness in the family, social, occupational or menstrual anamneses. She has always been well except for an attack of measles and chicken pox. The physical examination was without the finding of pathologic anatomy except for the rectum. Here there was an adenomatous polyp, the size and appearance of a small raspberry, $1\frac{1}{2}$ inches above the internal sphincter on the posterior wall. Examination of the remainder of the intestinal tract showed no other similar lesion and she was recommended to have this polyp removed.

On October 8, 1929, the polyp was excised with the removal and cauterization of the base. The first report made from the frozen section was that of benign tumor without degeneration. Subsequent study, however, revealed beginning carcinomatous changes in the base of the polyp; recommendation was made to sacrifice the anus.

She was placed on high caloric intake, mainly of fluid and semisolid nature and the colon was washed out twice daily. On October 11, 1929, a complete abdomino-perineal resection of the colon was performed. We were fortunate in securing an excellent induction of spinal anesthesia, so that the abdominal dissection was accomplished without inhalation anesthesia. The closure of the abdomen, and the perineal excision were done under nitrous-oxide-oxygen anesthesia. The postoperative condition was exceptionally free from violent reaction. No food or water were given by mouth for the first five days. During each twenty-four hours she was given 1 liter of 10 per cent glucose and 3 liters normal saline intravenously. On the seventh postoperative day the colostomy was perforated by cautery and the drain and three 2 inch iodoform gauze packs were removed from the perineal wound. A small amount of seropurulent fluid escaped with the gauze but this was apparently sterile

pus. Four cubic centimeters of 5 per cent mercurochrome were injected into the cavity, which promptly closed. The patient left the

FIG. 1. Adenomatous polyp on posterior wall of rectum. Base of polyp becomes carcinomatous in 50 to 60 per cent of all cases.

hospital with the wounds healed by primary intention and the colostomy acting nicely on October 31, 1929.

Benign tumors of the intestine are infrequent; but of all benign tumors, the adenomatous polyp is the most common. They occur usually in males of younger age and less often in women.

The etiology of these polyps is not clearly understood, though infectious or irritable colitis and long-standing constipation are considered causative. This patient had none of these predisposing factors.

The most important pathologic feature is that 50 to 60 per cent of these tumors become carcinomatous. They are usually situated in the large bowel but may occur in the small intestine. They are usually multiple but may occur singly as in this instance. Those adenomas located in the rectum are more likely to become malignant.

* Submitted for publication November 1, 1929.

The symptoms are not often striking. Bleeding from the rectum, as a solitary evidence of disease, is worthy of careful study of the entire intestinal tract. Occasionally slight indigestion, diarrhea, obstipation or even obstruction may occur.

The diagnosis is made only upon careful investigation of the alimentary tract when any of these symptoms cause the patient to seek advice. They may be mistaken for fibromas or myomas which come from different layers of the bowel; for hemangiomas which are extremely rare, and present the characteristic appearance of hemangiomas elsewhere. Lipomas also may be confused, though they originate from the fatty protrusions higher in the intestine and their appearance in the rectum would be unusual to say the least. The differentiation from malignancy is impossible without microscopic study. When the lesion is in the rectum and plainly visible, opinion may be erroneous. Where a large number of tumors is present, as in polyposis adenomatosis

intestinalis, the findings are usually benign, but even this picture may be carcinomatous. If a rectal polyp be examined and found benign, it may be assumed that the remainder of the nodes are benign.

The treatment of the condition will vary, of course, with the placement of the neoplasm. In any case, careful preoperative and postoperative attention, as already mentioned, is needed. The entire growth must be removed and especial effort made, if carcinomatous degeneration has commenced, to excise all the disease. With the bowel filled with polyps, ileostomy is done as performed by Lilienthal and Lockart Mummery; and a year later, the entire colon is resected. It seems that the resting of the colon may prevent formation of carcinoma. In the case cited, we were fortunate in finding a very early carcinomatous lesion and in being able to remove the diseased area entirely, with prompt convalescence. It may be hoped that the cure will be permanent.

FIBROADENOMA IN AN ACCESSORY BREAST*

RICHARD JOSEPH WHITE, M.D.

FORT WORTH, TEXAS

DELAFIELD and Prudden say:

Supernumerary mammary glands, polymastia, at one time considered comparatively rare are now known to be frequent; and the literature abounds with references to their occurrence in both sexes and on almost every portion of the body. In many cases these supernumerary glands are inactive but in females they may become functionally active at each pregnancy and differ in no way from the normally situated glands: in the male also these glands may secrete milk. *Adenoma or carcinoma may develop in them.*

Anyone who is aware of the condition has seen numerous examples of accessory breasts, mostly vestigial, represented by a rudimentary nipple, but this case is the

first I have seen of a tumor growing in the accessory breast.

Mrs. L. D., a young white woman, twenty-three years old, married, had had no pregnancies and had been thought by one doctor to have tuberculosis but this had been disputed by other very competent physicians. Two years previously she had been told by her family physician that two small brown spots below her breasts were accessory mammary glands. About two years ago she noticed a slight swelling in the region of the left accessory nipple and this had slowly but steadily increased in size until it had formed a considerable lump and was uncomfortable most of the time and quite painful when she was menstruating. She wanted it removed because it was uncomfortable and she feared cancer.

* Submitted for publication August 13, 1929.

Examination showed a pale, thin, flat-chested young woman with two normally developed breasts. About 3 in. below their lower borders in the nipple line were two rudimentary, small, brown, slightly elevated areas with a few hairs growing around them, obviously accessory nipples. Beneath the left one and extending below and to the outer side of it was a smooth mass shaped like half an egg cut longitudinally and firm and elastic to the touch. The skin over it was freely movable and it moved freely on the chest wall. It was slightly sensitive to pressure. There were no palpable glands in the axilla. No mass was palpable beneath the right accessory nipple.

The skin and subcutaneous tissue were infiltrated with procaine hydrochloride and a transverse linear incision was made with a small ellipse in its center, around the accessory nipple. The tumor was completely encapsulated and was shelled out very easily with practically no bleeding. The other accessory

nipple was excised and the incisions closed with a rubber dam drain to the tumor cavity for forty-eight hours. Both healed by primary union except that a little serum came from the drainage tract for five or six days. The tumor removed measured $6 \times 4 \times 3$ cm. and was slightly nodular on its superficial surface while its deep surface was slightly concave and fitted accurately the contour of the chest wall. There was everywhere a distinct capsule. It had a firm elastic feel. On section it was grayish white and very cellular in appearance. Microscopic sections showed an abundant fibrous stroma containing many glandular structures mostly small and of rather uniform size but some of them larger and of a less regular contour. They were for the most part lined with a single layer of cuboidal cells with a definite basement membrane everywhere and nowhere were there more than two or three layers of cells, a typical fibroadenoma as we see them in the fully developed breast.

SIMPLE LATERAL LUXATION OF THE ATLAS*

ARTHUR N. FOXE, M.D. and LEWIS J. FRIEDMAN, M.D.

NEW YORK

IN 1907, Corner¹ drew attention to the frequency of simple rotary dislocation of the atlas. Although the diagnosis is relatively simple when thought of, most of the reported cases have only been diagnosed at the autopsy table. Scattered communications stress the clinical features and describe the difficulties of radiological diagnosis. Jackson,² in 1927, was able to collect 27 simple cases in a wide study of the literature. He had seen 4 cases, in none of which the diagnosis had been made by the physician in charge. Simple lateral luxation of the atlas has not yet, as far as we could learn, been described.

This report is made in view of the apparent infrequency and yet claimed frequency

of simple atlas dislocations; and the interesting diagnostic problem and radiological findings that were present.

CASE 1. R. M., aged thirty-five, was admitted to the hospital on May 21, 1929. Her chief complaint was inability to use the left arm and leg. The past history was negative except for rheumatic fever at the age of twenty. The present illness began six weeks before admission with a recurrence of rheumatic joint involvement. Two days before admission the patient felt faint, lost consciousness and fell across the bed. On admission the physical examination showed a well-nourished adult female, distinctly stuporous. Questions put to her received only vague mumbled responses. The skin was generally moist, that of the face both moist and greasy. There was a left hemiplegia with supranuclear facial paresis, absent left abdominal reflexes and a bilateral Babinski sign, more marked on the left. At

¹ Corner, E. M. Rotary dislocations of the atlas. *Ann. Surg.*, 45: 9, 1907.

* From the Fourth Medical Division and Department of Radiology, Bellevue Hospital, N. Y. Thanks are due Dr. Alexander Lambert for permission to make this report. Submitted for publication August 20, 1929.

the apex of the heart there was a presystolic and systolic murmur with systolic shock; at the base, accentuation of the pulmonary

was $\frac{3}{8}$ inch. A tender mass was noted at the angle of the right mandible. Diagnosis: Adenitis with secondary trismus.

FIG. 1 A Upper cervical vertebrae in normal position. B. Rotary luxation of atlas. C. Lateral luxation of atlas.

second sound. There were occasional extrasystoles. Spinal puncture showed a blood-tinged fluid under slightly increased pressure. Diagnosis: Subacute bacterial endocarditis with cerebral embolus.

FIG. 2. Upper cervical vertebra of case reported. A, transverse process which was palpable, as described in text.

On May 27 the patient was more bright and it was noted that she held her head in a peculiar position. The face was turned moderately to the left, but somewhat awry so that the axes of head and trunk formed an obtuse angle to the right. The normal position of the head could apparently be actively restored by the examiner but it would soon resume the abnormal one. In these maneuvers the head was rotating on the lower cervical vertebrae. The mouth could hardly be opened. At most, the distance between upper and lower teeth

The condition persisted; the patient could not be fed adequately. A more careful examination now showed that the supposed gland was bone, and probably the transverse process of the atlas. On the left side, a depression was felt behind the angle of the mandible. Normally the transverse processes may be felt deep and high between the angle of the mandible and the mastoid process. Posteriorly the spine of the atlas was palpated somewhat to the right of the mid line. Neither at this time nor any subsequent time were cord, root, or nerve involvements present.

Clinical Diagnosis: Rotary dislocation of the atlas.

Roentgen-ray Diagnosis: Lateral luxation of the atlas.

The literature and radiological evidences of this condition were now investigated. It was impossible to correct the dislocation due to the seriousness of the patient's condition. The temperature fluctuated between 101° and 103°F. ; decline was gradual, and the patient died on June 18. No autopsy was obtained.

CLINICAL FEATURES

Rotary dislocation of the atlas is usually unaccompanied by cord or root involvement. The condition may be chronic for years in ambulant patients. The primary injury may be trivial. The degree of dislocation varies in different patients. The case reported clinically gives features identical with those described in rotary disloca-

tion of the atlas. It is unusual in that it occurred in a fall due to a cerebral accident in the course of subacute bacterial endocarditis. It showed the cardinal features of simple rotary dislocation and lateral luxation; deviation of the head, trismus, and palpable displacement of the transverse and spinous processes of the atlas. It was impossible to examine the atlas by oral palpation due to the extreme trismus. It is possible that if more frequently considered, the condition would be more frequently diagnosed. It is also possible that certain cases previously described as rotary dislocation really were lateral luxation.

RADIOLOGICAL FINDINGS

While there is no doubt that luxation of the atlas can be diagnosed clinically, the differentiation between the simple lateral and rotary lateral can be made only radiographically. The former condition when present is more difficult to recognize in view of the slight abnormal findings. The rotary lateral luxation produces so much

distortion that its presence is readily recognized on the radiograph. This can be seen on the accompanying photographs of experimentally produced luxation of a dried specimen of vertebrae.

The cardinal signs in lateral luxation of the atlas are: (a) the obliteration of the transverse process on one side; (b) the malalignment of the articulating surfaces of the atlas and axis; (c) eccentric situation of the odontoid process.

These findings can be seen only in the anteroposterior position. The lateral view of the cervical spine does not show any abnormality.

SUMMARY

Simple lateral luxation of the atlas, a case of which is here reported, has to our knowledge not yet been described. Simple dislocations of the atlas are said to be more frequent than generally believed. The recognition of this condition is not difficult when considered in the differential diagnosis both clinically and roentgenologically.

OSGOOD-SCHLATTER'S DISEASE*

G. H. V. HUNTER, M.D., F.A.C.S.

BROOKLYN, N. Y.

SINCE Osgood described this condition of the tibial tubercle,¹ different writers have written of it and reported cases. As it is of more common occurrence than is generally supposed and is frequently overlooked by the busy practitioner, I am taking the liberty of citing the following cases, which have come under my observation recently. In all these cases the patients were young and active in school sports and attribute the condition to violent exercises. There was a history of pain during or following the engagement in some strenuous exercise. In Osgood's original article

he drew attention to the fact that generally the tubercle of the tibia is developed from the upper epiphysis of the tibia and comes down in a beak-like projection which begins to unite to the shaft about the age of puberty. In rare cases the tubercle is developed in a separate center. To the tip of the tongue-like projection the fibers of the patella ligament are attached and during violent exertion it is quite easy for a portion of the bone to be torn away.

CASE I. F. T., aged fifteen years, was seen by me on May 7, 1927, with a history of pain over the tubercle of the tibia, of four months' duration. It was first noticed while wrestling

¹ *Bost. M. & S. J.*, 1903.

*Submitted for publication September 19, 1929.

FIG. 1. Appearance of normal tubercle of tibia of boy aged fifteen years.

FIG. 2. Case 1. Left knee. Note irregular appearance of tubercle with tearing-away of small portion.

FIG. 3. Case 1. Three months later. Note bone proliferation.

FIG. 4. Case II. Left knee. Tubercle attenuated with few fibers pulled away.

with another boy at school and gave considerable pain, which was relieved somewhat by rest. Pain remained and was especially noticed in going up and down stairs. On examination the tibial tubercle was found tender and swollen and there was some pain on flexion but less on extension. A roentgenogram taken at that time showed the peculiar thinning-out of the tubercle of the tibia with a moth-eaten appearance, quite different from the normal beak-like projection, as seen on the opposite tibia. The treatment was immobilization in a plaster cast, from midcalf to midthigh, first placing a piece of split felt over the tubercle and fixing with adhesive, then protecting the limb with cotton. This dressing was applied with the knee extended and caused little if any inconvenience, allowing the patient to walk on it and attend school duties. Cast was left on one month, then removed and reapplied. Patient stated that the pain disappeared immediately following the application of the cast. The second cast was allowed to remain on for five weeks and then removed. Following this the patient wore a bandage during the day only and the pain never reappeared. Three months from the time the first roentgenogram was taken, a second one was made, showing the thickening of the tubercle by bone callus. At this time there was no pain on pressure and no symptoms were elicited by extreme flexion or extension.

CASE II. W. B., aged fourteen years, was first seen on October 29, 1927 with a history of injury during a basketball game, three weeks before. The typical symptoms of pain on pressure and on going up and down stairs were complained of and the roentgenogram showed the same thinning-out, irregular appearance as shown in Case I. The treatment was identical and roentgenograms taken three months later showed a much different appearance than on the first examination. Here too we find much bone callus thrown out and the tubercle was not tender on pressure. The patient was symptom-free and discharged.

CASE III. A girl, aged fourteen years, hurt her knee in a gymnasium and gave the classical symptoms. Examination showed the same tenderness on pressure over the tubercle, which seemed swollen and there was pain on flexion and extension. Roentgenograms revealed the same appearance as seen in the former cases. Treatment instituted was immobilization in

plaster, changing the plaster at the end of five weeks. The patient then wore a bandage for five weeks after removal of the second cast.

FIG. 5. Case II. Note thinning out of tubercle.

A final roentgenogram shows the same bone formation as seen in the other two cases. Patient was discharged at the end of three months, symptom-free.

I have kept in touch with these cases since discharge and there has been no return of symptoms.

CONCLUSIONS

1. A tearing-away of part of the tubercle of tibia may occur with only a moderate amount of disability.
2. The accident is most likely to happen from the ages of twelve to sixteen and more especially in strong athletic types.
3. Immobilization in plaster cast for from two to three months will allow nature to heal the lesion.

VESICAL NECK OBSTRUCTION WITH LARGE VESICAL CALCULUS. BILATERAL HYDROURETERS

WITH HYDRONEPHROSIS. DOUBLE LEFT KIDNEY AND URETER*

CLARENCE G. BANDLER, M.D., F.A.C.S. AND JOSEPH A. HYAMS, M.D., F.A.C.S.

NEW YORK

THE subject of this communication, (B. B.), is a young, poorly nourished man, 25 years of age, who was admitted

FIG. 1. Roentgenogram showing shadow of large calculus.

to the Urological service of the New York Post Graduate Hospital in July, 1928. The patient's complaint was painful micturition, which symptom had been constant for a period of 5 years. This pain was continuous throughout the act, and was particularly severe at the termination of the flow. No urethral discharge nor hematuria had been observed, but the stream was markedly diminished both in size and force. The patient voided about four times during the day, and there was frequency of four or five times at night.

Previous history revealed no evidence of venereal infection, as the patient denied both gonorrhea and genital ulcer of any kind.

Family history bore no relation to his present illness.

Physical Examination. A young man, some-

what emaciated, of rather sallow complexion and very anxious mien, who evidently had lost considerable weight. Eye examination is negative. Nose and throat reveal an atrophic rhinitis on the right side, with muco-pus in small amounts exuding from left turbinate bone. Uvula was markedly elongated and reddened, while the tonsils were deeply imbedded and congested, and a moderate amount of purulent material was expressed therefrom. The pharynx was congested, and the epipharynx was dry with crust formation. Diagnosis of subacute tonsillitis and pharyngitis was made from the aforesaid findings, and local treatments were immediately instituted. Heart and lungs were essentially negative. Abdominal examination revealed two palpable and movable kidneys, which were moderately tender. Palpation of the suprapubic area elicited tenderness over the bladder on both moderate and deep pressure. Rectal examination was negative, as was the examination of both extremities. Reflexes were moderately exaggerated. Temperature was 100.8°, pulse 100 and respirations 20. Three days after admission, routine x-ray examination of the genito-urinary tract, showed marked bilateral nephroptosis, with the shadow of a large round calculus in the bladder. (Fig. 1.)

Cystoscopic examination was performed under caudal anaesthesia, due to spasm at the internal sphincter and vesical intolerance. On introducing the cysto-urethroscope, its tip had to be elevated to override an obstruction, which, however, was overcome without difficulty. The bladder was of fair capacity, from which cloudy and purulent urine was obtained. The mucous membrane was inflamed throughout its entire extent. Two orifices of diverticula were observed mesial to the right ureteral opening. A large, rounded, movable calculus was seen, which obscured the interureteric ligament and the orifices of several diverticula. These were later demonstrated by a cystogram. The ureteral openings were normally placed, and both were visibly function-

* From the Department of Urology, New York Post Graduate Medical School and Hospital. Submitted for publication February 8, 1930.

ing. However, upon the administration of Indigo Carmine, intravenously, no dye appeared during the entire period of the examination, which was over fifteen minutes. On the right side of the internal sphincter considerable tessellated edema was observed. The sphincter itself, was somewhat rigid, the floor raised, but its elevation above the interureteric ligament could not be estimated, due to the calculus; the post-montan area (waterfall) showed a sharp descent to the verumontanum.

Diagnosis.—Vesical calculus; vesical diverticula and trabeculae with chronic cystitis; bilateral pyelonephritis; probable median prostatic bar.

While it was realized that the large vesical calculus was the result of the other pathologic conditions in the genito-urinary tract, it was deemed advisable to remove this calculus first, and put the bladder to rest by proper drainage. Accordingly, five days after admission, suprapubic cystotomy was performed, and a large calculus, the size and shape of a golf ball, was removed. (Fig. 2.) Convalescence was slow, and the wound drained urine for a considerable time. Catheter drainage was employed two weeks after operation, and it was observed that when the catheter was removed, the patient would complain of considerable pain in the right flank, and this was accompanied by a rise of temperature to 104°, with acceleration of pulse rate to 120. Re-introduction of the indwelling catheter was accompanied by cessation of pain, and diminution in temperature and pulse rate. Four weeks after operation, cystoscopy showed the bladder of fair capacity, with the trabeculae and diverticula as previously described, also the internal sphincteric condition as observed before, but more clearly delineated. Upon sealing the suprapubic open-

ing, a cystogram was made with 6 per cent sodium iodide solution. This showed a contracted bladder with multiple diverticula and

FIG. 2. Calculus removed from bladder.

trabeculae, also marked dilatation and tortuosity of the left ureter, and a moderate reflux up the right side. Indigo Carmine did not appear from either ureter in fifteen minutes.

Because of the very evident renal damage, and because of the persistence of the suprapubic fistula, all due, apparently, to the visible vesical neck obstruction, it was deemed advisable to reopen the bladder, and remove that obstruction. Accordingly, at this time, under general anaesthesia, the bladder was reopened, and a small piece of tissue was excised from the floor of the internal sphincter.

The pathological report of this specimen is as follows: the epithelium is hyperplastic, with no visible glandular structure. The submucosa shows a rather thick layer of fibrous tissue which is rich in small and large blood vessels. The walls of the vessels which are nearer the mucosa seem to be thicker than those which are situated more deeply. The vessels nearer the mucosa are small capillaries, while rather thick-walled arteries are seen in the deeper tissue. There are one or two areas of round celled infiltration. In the depth of the specimen, there are hypertrophic muscular fibres, with a small amount of perivascular infiltration. (Fig. 3.)

The whole picture is that of:

- (a) Hypertrophic musculature.
- (b) Secondary submucosal chronic inflammation, which is superficial.

FIG. 3. Low power photomicrograph of tissue removed from internal sphincter.

- (c) Inflammation and fibrosis superimposed upon the congenitally hypertrophied sphincter; with most of the inflammation in the superficial areas.

Pathological Diagnosis. Fibrosis of bladder neck.

Because of secondary hemorrhage, it was necessary to reopen the wound twelve hours after this operation, and moderately pack the base of the bladder. Transfusion was given at this time, followed by intravenous infusions of glucose in saline solution, and on the day following this operation, another transfusion was administered. The patient's general condition was poor, the temperature ranging from 101° to 103° , with an occasional excursion above 104° , on one occasion to 106° . There was coincidental marked acceleration of the pulse rate.

Blood chemistry studies, instituted at this time, (Table 1), showed a very definite uremic

acidosis. This condition lasted for about two weeks, and was energetically treated by the administration of weak glucose solution, with bicarbonate of soda. Urine excretion was entirely suppressed on August 28th, and severe post-operative hemorrhage followed resection of a congenital band at the internal vesical sphincter. For this hemorrhage a transfusion of 500 cc. of blood was given on August 28th, followed by a transfusion of an equal volume the following morning. The anuria persisted during August 29th, when the blood urea nitrogen had risen to 27.4 and the uric acid to 6.0 mg. per 100 cc. A moderate acidosis was indicated by the carbon dioxide combining power of 33.8 volumes per cent. A mild hyperglycemia, (0.165 per cent) was also noted coincident with a temperature of 105° . This increased blood sugar is no doubt dependent upon the acute infection. An infusion of 1000 cc. of physiological salt solution containing 1 cc. of 1:1000 adrenalin solution preceded the introduction of the Levine duodenal tube. Magnesium sulphate was first administered through the tube, followed by 500 cc. of tap water, and 500 cc. of 5 per cent glucose solution containing 1 per cent sodium bicarbonate. The intraduodenal infusion of glucose and sodium bicarbonate was repeated four hours later. Blood urea nitrogen on August 30th, had risen to 43.8 mg., the uric acid to 7.4 mg. but the carbon dioxide combining power had been elevated to 38.1 volumes per cent. A small volume of bloody urine was obtained during this day, and another litre of glucose and sodium bicarbonate solution was administered through the duodenal tube. However, the blood urea nitrogen continued to rise, reaching its maximum at 62.5 mg. per 100 cc., on September 1st. A creatinine of 4.5 mg. per 100 cc. was obtained on August 31st, and uric acid of 7.2 mg. per 100 cc. The carbon-dioxide combining power of the blood of August 31st, was 43.8 volumes per cent. During the first twelve hours of August 31st, the volume of urine drained was too small for estimation, but for the latter twelve hours of the day 210 cc. of urine drained, which was the first measurable quantity of urine excreted during a period of 72 hours. The total intake of fluid for August 31st, was 4,000 cc. Frequent liquid stools were passed during the 72 hours of urine suppression, and we believe the excretion of an abnormal amount of fluid by the intestinal tract served to diminish the accumulation of nitrogenous waste products in the blood. Moreover, the use of physiological

salt solution in hypodermoclysis and intravenous infusions maintained the blood chlorides within normal limits despite the loss of chlorine

erated production of creatinine from creatine consequent with the increase in body temperature causes the persistence of a high blood

FIG. 4. Complete urographic study, resulting from vesico-renal reflux of 6 per cent sodium iodide solution. This picture was made prior to complete removal of obstruction at internal vesical sphincter.

FIG. 5. Urographic study with 6 per cent sodium iodide solution revealed no vesico-renal reflux, 1½ years after removal of obstruction at internal vesical sphincter.

in the vomitus, and thus obviated the production of an alkalosis. The patient's general condition on September 2d, indicated definite clinical improvement, the volume of urine rising to 2,100 cc. Thence, the duodenal tube was removed, and thereafter fluids were given by mouth, supplemented by hypodermoclysis of 5 per cent glucose in physiological salt solution. On September 4th, the blood creatinine rose to 8.9 mg. per 100 cc. although the urea nitrogen had shown a steady decrease from 62.5 to 54.8 during the preceding 48 hours. However, six days later the creatinine had fallen to 5.3 mg., with urea nitrogen of 56.6 mg. per 100 cc. A continuous decline in urea nitrogen of the blood to 16.0 was noted for the subsequent 8 days, but the creatinine remained above normal, fluctuating from 5.3 to 3.7 mg. per 100 cc. During the period from September 2d until September 26, the body temperature varied from 101° to 105°, and the peaks in the temperature curve were followed by chills. An accel-

erated production of creatinine from creatine consequent with the increase in body temperature causes the persistence of a high blood creatinine. A periurethral abscess was incised and drained through the perineum on September 18th, and a few days later a lumbar abscess was incised, the culture of contents showing paracolon bacilli and non-hemolytic streptococci. Blood culture, however, gave no bacterial growth. Thereafter the temperature ranged from 99° to 100°. For a period of 72 hours, from September 21st to 24th, during an attack of acute pyelitis of left kidney the volume of urine voided fell to 300–500 cc., and this oliguria was accompanied by an increase in urea nitrogen of the blood until September 26th. From the time of the cystotomy until October 22d, the urine was drained through a Ritter tube in the suprapubic wound. On October 22d, the Ritter tube was removed, and thereafter the urine was voided per urethram. The volume of urine excreted daily after September 26th approximated the total fluid intake. Chemical blood analyses made at intervals of from 4 to 7 days from September 26th

until November 9th gave normal figures for urea nitrogen, creatinine, sugar and carbon dioxide combining power of the plasma. However, the renal function was still definitely impaired. For several months attempts to estimate renal function by colorimetric methods revealed amounts too small for measurement. The hyperchloremia noted in the last of these specimens was due to a decrease in erythrocyte volume, associated with a moderate secondary anemia. After October 1st, the patient was on a high caloric diet, and spent the greater part of the day out of bed on the roof.*

X-ray studies on frequent occasions by means of cystography always showed marked vesico-renal reflux on each side, with clear delineation of the bladder, ureters and kidneys; with a very evidently contracted bladder, showing multiple diverticula and trabeculae; and with marked bilateral ureteral and renal pelvic dilatation and left ureteral and renal duplication. (Fig. 4.) This patient's convalescence was very slow and most gradual, and the suprapubic sinus persisted for months. In November, 1928, four months after admission to the hospital, cystoscopic punch procedure was performed, which removed the remaining portion of the median bar. So thoroughly was this done, that within two weeks after this operation the

suprapubic wound was closed. While the wound reopened on two occasions within the next month, it has remained permanently closed for the past year. After five months of hospitalization, this patient was discharged from the hospital, although he had very definite evidence of moderate pyonephrosis of the double left kidney, and pyelonephritis of the right kidney. He has continued to improve most remarkably and has gained over fifteen pounds in weight in the past six months. During this time he has followed a most arduous occupation in an airplane factory, and has not been called upon to give up his occupation at any time because of any physical infirmity. One month after leaving the hospital, urea nitrogen and CO₂ combining power determinations were well within normal limits. For the first time in six months, phenolsulphonophthalein appeared in about 17 per cent in two hours.

P.S.P. test made on January 31st, 1929, was as follows:

Spec. 1st half hour Vol. 15 cc. P.S.P. trace
Spec. 2d half hour Vol. 125 cc. P.S.P. 8.9 per cent
Spec. 3d half hour Vol. 65 cc. P.S.P. 5.11 per cent
Spec. 4th half hour Vol. 48 cc. P.S.P. 3.9 per cent

Our patient has been observed at occasional but regular intervals since he left the hospital, and a marked decrease in the frequency of micturition has been noticed. Cystoscopic examination reveals very little vesical change, although there is no obstruction of any kind at the internal sphincter or on the floor of the prostatic urethra. Urine examination shows a faint trace of albumin, with fifteen to twenty pus cells per high power field. Within the past two weeks, blood chemical study showed a return to within normal limits, and the phenolsulphonophthalein output was 47.1 per cent in two hours, consisting of 13.4 per cent in the first hour and 33.7 per cent during the second hour. Upon the day of this test, a cystogram with 6 per cent sodium iodide solution was made, which revealed no evidence of vesico-urethral obstruction; a somewhat larger bladder capacity than heretofore, with no vesico-renal reflux, although there is some evidence of ureteral dilatation for a short distance on each side. (Fig. 5.)

CONCLUSIONS

(1) A patient is presented with very definite evidence of vesical neck obstruction, giving rise to vesical and renal pathol-

* We desire to express our thanks to Professor John A. Killian of the Department of Biochemistry, for the above blood chemistry studies and their interpretation.

ogy in the presence of a left ureteral and renal anomaly.

(2) Marked renal insufficiency with definite surgical pathology has been completely relieved by removal of the vesical neck pathology.

(3) Essential surgery was followed by prolonged convalescence with subsequent complete improvement of the patient.

DISCUSSION

DR. JOSEPH A. HYAMS. From the history, associated congenital abnormalities of the urinary tract, and cysto-urethroscopic examination, the obstruction at the vesical neck could be classed as congenital in origin. The microscopic examination confirmed the clinical observation and showed an hypertrophic musculature with secondary submucosal chronic inflammation superficial to it. There was inflammation and fibrosis superimposed on the congenital hypertrophy of the sphincter with most of the inflammation superficial, with a gradual decrease toward the deeper structures. The vessels near the mucosa were small capillaries with rather thick walled arteries in the deeper tissues, conforming to the congenital type of sclerosis described by Herbst and others. Herbst, however, believes that this type of congenital muscular hypertrophy is the cause of all cases of fibrosis of the vesical neck, wherein an hypertrophied sphincter muscle, due to continuous congestion and inflammation, later becomes fibrosed. This has not been verified by our examination of ten specimens removed from known cases of median

bar and coarctation of the vesical neck. Inflammatory fibrosis has been found to be a far more frequent cause for this condition.

A possible explanation for the bleeding which occurred after the suprapubic removal of the wedge shaped piece of tissue, is found in the large number of good sized vessels seen in the base of the microscopic section of the excised tissue.

The co-existence of median bar and vesical calculus is not unusual. Young, in a study of 209 cases of median bar, found calculus present in 20 per cent, whereas diverticulum of the bladder was observed in 30 per cent. The latter is conceded to be a very frequent associated abnormality.

An important element in the prognosis of vesical calculus is the co-existence of median bar or congenital pathology which may be present and is not noted unless no detail of history and physical examination is omitted, and a complete urological examination is carried out.

In a case reported by Mathé, the procedure followed in our patient was unfortunately reversed. The patient, 41 years of age, was compelled to begin catheter life at 21 years of age; no relief was obtained by cystotomy, and a later perineal exploration of the prostate, and at a still later date, nephrectomy. Finally a v shaped trough was made in the median bar, and his symptoms were relieved.

In our case, the kidneys may be said to be in a state of renal compensation. With congenital and acquired pathology, and infection still present in the urinary tract, any disturbance of this delicate balance is to be expected at any time.

HEADACHE (POST-TRAUMATIC)

RELIEVED BY LUMBAR AIR INSUFFLATION REPORT OF A CASE*

H. L. SKINNER, M.D.

SAVANNAH, GA.

POST-TRAUMATIC headaches when not secondary to fracture are usually diagnosed as meningeal headaches, traumatic neurosis, or malingering, according to the severity of the injury and symptoms. All who have done any accident or industrial surgery have been in doubt how to classify this type of case and have found the relief of the symptoms difficult.

During encephalographic studies different observers have noted that some patients with chronic headache were relieved, but it was not until Penfield¹ reported the use of lumbar air insufflation for the treatment of headache, that this method was clearly described as a therapeutic procedure.

The following case is reported for the purpose of again inviting attention to the satisfactory results obtainable by this method in otherwise intractable cases.

J. G., colored male, aged forty-two, occupation carpenter, admitted to U. S. Marine Hospital, Savannah, Georgia, October 24, 1928 for examination to determine right to compensation under National Employees' Compensation Act.

History. In February 1924, while employed, was struck on the vault of the skull, left frontoparietal region, by a heavy timber. There was no bleeding from the nose, mouth or ears, and examination at this hospital the following day showed no evidence of fracture of skull. At that time vision was normal, eye grounds were normal, hearing was normal, and there was no evidence of damage to the middle ears. Later examination showed that he had albumin and casts in the urine; that there was thickening of the superficial vessels with blood pressure of 144 systolic and 108

diastolic; and that the Wassermann reaction was plus 3. Since the injury he has been unable to work on account of continuous pain in left side of head. The pain has been dull in character with occasional sharp darting pains, and has been increased by movements, especially stooping.

The patient has been under observation here and occasionally hospitalized ever since the injury. Treatment has been antisyphilitic and directed toward relief of the symptoms of nephritis and arteriosclerosis.

Chief complaint on admission was continuous headache and dizziness.

Physical examination on admission shows a fairly well developed, slender man, weight 145 lbs., height 5 ft. 11 in. Head is normal in contour and without scars, tenderness, or evidence of injury. The hearing in the left ear is somewhat impaired. Pupils are equal and small, reacting to light and accommodation. Vision 20/70, each eye unimproved by lenses. Eye grounds show optic atrophy bilateral and arcus senilis is present. There is no evidence of paralysis of the face or deviation of the tongue. The deep and superficial reflexes are normal. The only other positive finding is thickening of radial and brachial vessel walls.

Laboratory findings are: Urinalysis negative; feces negative. Wassermann reaction 3 plus on one occasion and negative on two occasions. Spinal fluid: Wassermann reaction negative; cell count normal; globulin negative, and no mastic curve.

X-ray of the skull showed a slight depression of the vertex at the junction of the frontal and parietal bones which may possibly be due to an old fracture. This depression disturbed the continuity of the inner table. There was no other deformity present.

In comparing the findings in this case with those reported in the literature, we concluded that the patient might be susceptible to relief by air insufflation which was undertaken on November 23, 1928.

The procedure was carried out under aseptic

¹ Penfield, W. Chronic meningeal (post-traumatic) headache and its specific treatment by lumbar air insufflation; encephalography, *Surg., Gynec. & Obst.*, 45: 747, 1927.

* Submitted for publication August 1, 1929.

conditions in the operating room, the patient being given $\frac{1}{4}$ grain of morphine before leaving the ward. He was placed on his right side with head elevated about 30° and brow pointing upward. The spinal fluid pressure was 14 mm. Hg. The fluid was withdrawn in 5 c.c. amounts, 5 c.c. of air which was filtered through cotton being injected after each withdrawal. Before starting, we made sure that all connections were air tight and syringe tight-fitting. Eighty cubic centimeters of fluid were removed and replaced with 70 c.c. of air. During the procedure patient complained of severe pain in left side of head.

Without changing his position, he was sent to the x-ray room and the usual skull pictures taken. On changing position of head, patient became very nauseated and pain more severe.

After x-ray plates were taken, he was placed in bed with low blocks under head of bed. He was directed to lie on right side in order to keep left side of head uppermost, that side being the one where the headaches were more severe and constant. For five days patient complained of headache in left temporal region and top of head, describing it as dull in character except when moving head, at which time it became sharp and shooting in character. He was kept in bed until headache disappeared. The x-ray showed air scattered throughout the subarachnoid space, especially the left side, and no cyst formation was seen. He was discharged free from headache and dizziness on December 11, 1928. Five months later he was seen, and had suffered no recurrence of headache or dizziness.

DEPARTMENT OF RADIOLOGY

JAMES T. CASE, M.D., F.A.C.S., EDITOR

FUNDAMENTALS IN ROENTGENOLOGY OF THE COLON*

JAMES T. CASE, M.D., F.A.C.S., D.M.R.E.

CHICAGO, ILL.

THE roentgen-ray study of the colon is one of the most interesting investigations in the field of diagnosis, but its success is in a high degree dependent upon the skill and experience of the individual radiologist. The roentgen findings are susceptible of so many plausible but erroneous interpretations that it behooves one to become as familiar as possible with the physiological variations of the normal colon, especially relating to its motor behavior, in order to interpret properly the findings in a given case. There are very many variations of the normal and a great many pathological conditions which simulate various phases of the normal.

TERMINOLOGY

For convenience, as well as for anatomical reasons, it is proper to divide the large intestine (Fig. 1) into: (a) the cecum, that portion of the large bowel proximal to the ileocolic junction; (b) the ascending colon, from the ileocolic junction to the hepatic flexure; (c) the transverse colon, from the hepatic flexure to the splenic flexure; (d) the descending colon, from the splenic flexure to the level of the crest of the left ilium; (e) the iliac colon, from the left iliac crest to the iliopectineal line; (f) the pelvic colon, from the iliopectineal line to the rectal ampulla opposite the third sacral segment. The junction between the iliac and the pelvic colon may be termed the ilio pelvic junction, and that between the pelvic colon and the rectum the pelves rectal junction. The term sigmoid, which includes both the iliac and the pelvic colon, does not find a place

in the more convenient terminology given above.

ANATOMICAL CONSIDERATIONS

In its roentgenological aspects the large intestine is easily distinguishable from the small, both by its greater size and by the characteristic haustral sacculations which occur through the large bowel with the possible exception of the lower pelvic colon and rectum.

The colon represents about one-fifth of the whole extent of the intestinal canal, being on an average $4\frac{1}{2}$ to 5 ft. in length. Extremes have been recorded from 3 ft. to more than 6 ft. The caliber of the colon varies considerably according to whether it is visualized by an opaque enema or by ingested opaque material. After the injection of 1200 c.c. of opaque enema, the following may be considered as the average diameters of the normal colon on a roentgenogram made at a focus-skin distance of 65 cm., the patient lying prone upon the film: cecum 6.0 c.; ascending colon 5.0 cm.; transverse colon 5.0 cm.; descending colon 4.5 cm.; iliac colon 4.0 cm.; pelvic colon 3.5 cm. These figures were arrived at after measurement of a series of normal colons.

OPAQUE MEAL OR OPAQUE CLYSMA IN STUDYING THE COLON

Following an opaque meal, the measurements of the colon vary considerably from the foregoing estimates, and yet one must admit that the exact caliber of the lumen of the bowel as it ordinarily exists is much more faithfully recorded after an opaque

* Received for publication March 20, 1930.

[This is the first of a series of papers by Dr. Case on the Roentgenology of the Colon. The next will appear in an early issue.]

meal than after a barium enema. In fact, for the study of the colon it appears to the writer that one should employ both

The enema may cause a totally abnormal filling, and in nervous individuals it may produce exaggerated intestinal tonicity

FIG. 1 Illustrating the divisions of the colon according to the newer terminology. Instead of *sigmoid*, we speak of the *iliac colon*, from the iliac crest to the iliopectineal line, and of the *pelvic colon*, from the iliopectineal line to the junction with the rectal ampulla opposite the third sacral segment.

the opaque meal and the barium clysma, especially if one is interested in a study of colonic function. It does not seem possible to arrive at worthwhile conclusions regarding the function of the colon from the opaque enema study alone. Both the meal and the enema are essential. It is hard to believe that there is any appreciable difference in the size, form and position of the colon under the supposed "weight" of an ordinary non-opaque meal and that of an ordinary meal into which has been stirred 2 to 4 c.c. of barium sulphate. On the other hand, how distorted the clysma-filled colon (Fig. 2) may be, is easily demonstrated by comparisons of a few roentgenograms of the clysma-filled and the meal-filled colon.

FIG. 2. Appearance of enema-filled colon, with marked distortion of the proximal colon due to overdistention.

to such a degree as to simulate spastic conditions or even organic constrictions. In fact, the opaque enema influences the colon in almost every respect in an entirely different manner from the opaque meal. With the former, haustral markings are nearly always absent; with the latter the haustral segmentation is always present except during the short period required for the execution of the spontaneous mass movements which constitute the principal propulsive activities of the colon. The position of the enema-filled colon is often abnormal, especially when the rectal injection has been made with the patient in the knee-chest position. The transverse colon, particularly, may be shortened and raised, presenting an appearance very different from that seen in the case of the functioning bowel. The knee-chest position for the introduction of the opaque injection is quite unnecessary, for unless there is some gross obstruction the colon fills easily when the patient lies supine. The use of the Trendelenburg position may lead to serious misapprehension as to the morphology of the colon.

POSITION OF THE NORMAL COLON

The average colon in health (Fig. 3) may be described as follows: With the

crests, although in this same type of individual the transverse colon may lie well above the navel when the patient

FIG. 3 Appearance of average colon of normal individual, after careful filling by opaque enema, care being exercised not to overdistend. Compare with Fig. 3.

patient standing, the lower border of the cecum reaches as low as the right iliopectineal line, the hepatic flexure extends upward as far as the costal margin, and the splenic flexure reaches as high as the lower border of the spleen. The level reached by the lower border of the transverse colon varies considerably in different patients as well as at different times in the same patient.

The shape of the colon in average normal individuals varies considerably with the physical type: in short, stocky people tending to obesity (Fig. 4) the transverse colon, as well as the lower border of the stomach, is usually high, the lowest point of the transverse colon approaching a line joining the iliac crests; whereas in tall, slender individuals the transverse colon is likely to be v-shaped or u-shaped, its lower border normally reaching several inches below the line joining the iliac

FIG. 4. The enema-filled colon of an obese individual.

lies supine, or when the pelvic loop is well filled.

MOBILITY OF THE COLON

The colon should be freely movable throughout at all points which can be reached by the examining finger (of course, with the protection of a leaded glove) palpating under the guidance of the fluoroscopic screen. It should be possible to move the tip of the cecum and the terminal ileum for 2 or 3 in. in all directions. The ascending colon should be movable laterally for an inch or two, at least; often it and the cecum are extremely mobile. The hepatic flexure is not often within reach of the palpating fingers, although at times the right half of the colon is so very mobile that the cecum, ascending colon and hepatic flexure all can be pushed over to the left side of the midline. The transverse colon itself is rarely adherent; sometimes it is bound down in certain positions by adhesions of the omentum secondary to inflammatory disease or operative fixation of the omentum. The two legs of the hepatic loop, that is, the upper part of the ascending colon and the first part of the transverse colon, should be freely separable from each other. The same is true of the two legs of the splenic

loop, although it is extremely rare for adhesions to exist between the two legs of the splenic flexure. The descending

Indeed, in those days little was appreciated of the great value of the opaque meal examination in discovering ulcer and carci-

FIG. 5. Drawings from Schwarz illustrating variations in the disposition of the hepatic flexure.

and the iliac colon are usually fairly well movable, except at the junction between the two, the iliopelvic junction, where the mesocolon is normally very short. The mesocolon is also very short at the pelvirectal junction, but the pelvic colon itself should be very freely movable. In heavy patients it is not always possible to test the mobility of the pelvic colon by actual manipulation of its loops; but even in these cases, accurate deductions can be drawn for a comparison of the height reached by the pelvic loop during the filling of the colon by enema with that reached by it, following visualization by an opaque meal.

THE POSITION OF THE VARIOUS SEGMENTS OF THE COLON

In the early days of roentgenology the position of the colon, especially of the transverse portion, was a matter of considerable concern. It was perhaps the coincidence of the work of Glenard and the discovery of the x-rays which combined to impress undue importance on the morphological aspects of the abdominal viscera.

noma of the stomach and bowel; the determination of the position of the lower border of the stomach was the principal object of the x-ray study. As late as 1915 there were still relatively few who appreciated the tremendous importance of the investigations of Rieder, Holzknacht, Haudek, L. G. Cole, Pfahler and others in advancing roentgenology of the stomach from the stage in which interest centered on morphology to the high plane of ulcer and cancer diagnosis. In that year (1915) the following passage was printed in a prominent American medical journal: "The patient was brought in for a roentgen examination. The mixture of 3 oz. of barium sulphate and 12 oz. of buttermilk was given him and after a few minutes, a large picture of the abdomen was taken to *locate* the stomach." (*Italics our own.*)

Four hours after the meal, the protected palpating hand, pressing over the right lower abdomen, can separate the terminal ileum from the cecum and permit a study of their contours and mobility. The appendix may also be seen at this hour, though the eight-hour, or the twenty-four

hour observation is more propitious for finding and studying the appendix, and in many cases the later observation is better for investigating the cecum. Usually the lower end of the cecal shadow in the erect position lies about 2 cm. below the iliopectineal line. The cecum has a rounded form and is usually mobile in all directions because of its relatively long mesentery. The shape and position of the cecum is extremely variable in different individuals: the high cecum held up by congenital shortening of the ascending colon; the "cecum mobile" which is frequently found in the true pelvis instead of the right iliac fossa and all the different grades between these two extremes. Incomplete rotation of the colon, presenting an "inverted" cecum and other aberrations from the usual arrangement, will be discussed in a subsequent study.

The hepatic flexure varies considerably in length, position and in shape (Fig. 5). In some cases one sees the ascending colon merge directly into the transverse at a low point near the right iliac crest; in others there may be formed a loop of varying pattern which requires not only manipulation under screen guidance but also turning the patient in order to fluoroscope him at various angles.

In the transverse colon, one may see a variety of positions, not only in comparison of one patient with another but also in the same patient at different times. This will be fully described when discussing the large pendulum movements of Rieder (Fig. 6). Under palpation, on positional changes of the individual, and as a result of intrinsic peristaltic activities the transverse colon, even in the same individual, may assume all shapes from an almost straight w or a v to a stirrup-form or an inverted u. Rieder's large pendulum movements effect considerable change in position, curves and undulations of the intestinal tract without propelling its contents. All these changes are possible because of the long transverse mesocolon. As a rule, the transverse colon accompanies the

greater curvature of the stomach in any descent it may undergo. But, because of the variability of the length of the gastroduodenal omentum the reverse is not necessarily true: that a low position of the transverse colon means a low position of the stomach.

The splenic flexure is more nearly fixed than any other part of the colon; it is suspended high up near the left diaphragm, usually separated from it by the spleen, and forms what in the roentgenogram of the abdomen often looks like an acute angulation. As a matter of fact, this angle is seldom acute, as may be easily demonstrated by turning the patient somewhat on his right side. Lateral fluoroscopy shows very plainly that with very rare exceptions the splenic flexure forms a rather generous curve uniting the anteriorly located transverse colon with the posteriorly situated upper part of the descending colon (Fig. 7). Although the highest point of the splenic flexure usually coincides with the lower border of the spleen, one frequently sees the top of the splenic loop high up under the diaphragm, sometimes exhibiting marked redundancy. In case of such redundancy accumulations of gas in the splenic loop may cause real distress by knuckling the bowel sharply upon itself and producing a valve-like action with temporary obstruction.

The descending and iliac portions of the colon are usually short and straight, often empty and contracted, but sometimes containing the same kind of barium-mixed bowel content seen elsewhere. The descending colon is a conducting tube from the proximal colon into the lower sigmoid and rectal ampulla, and therefore often empty.

The pelvic colon is extremely variable in regard to size and position. In fact, it may be found in any part of the abdominal cavity. It may join the rectum either from the left or the right side or from above. The most common variations are illustrated in Figure 8. The pelvic colon may be very short, forming almost a direct line from the rectal ampulla

into the descending colon, a condition often encountered in obese individuals; on the other hand, it may be so long as to

TECHNIC OF THE ROENTGEN EXAMINATION

An earnest effort should be made to

FIG. 6. Tracings from a series of roentgenograms by Rieder made at half-hour intervals, all conditions being the same except for the influence of peristalsis. Note the changes in the position and shape of the transverse colon, which Rieder ascribes to the "large pendulum movements."

reach higher than the transverse colon, lying in the right or left subchondral regions. In one of our cases the pelvic colon at operation measured more than 56 in. in length, the top of the loop lying in the gallbladder region. Not infrequently the pelvic colon enters into the sac of a left inguinal hernia.

follow a routine technic, modifying or extending the routine in certain cases as the circumstances seem to demand. The writer insists upon the importance of a complete alimentary tract study in every case, even though the trouble may seem to be localized in some one portion of the digestive tube. So often

one finds important bowel lesions clinically diagnosed as gastric disorders, and vice versa. Right upper quadrant symptoms,

FIG. 7. Tracings showing that the splenic flexure usually forms a rather generous curve, when seen in the lateral projection, although in the anteroposterior projection it may simulate a rather sharp angulation. (After Schwarz.)

without any discernible organic basis, are extremely common in cases of lower bowel organic or functional disease and may be very misleading. Except in emergency cases, such as suspected acute obstruction, it would seem desirable that sufficient time be allotted for an adequate routine study. This means that three days, sometimes a four, should be planned on for an adequate study of the colon. Less time will result in proportionately less reliable work. A study of the function of the bowel must be carried out upon the functioning bowel and during this investigation the patient should carry on as nearly as possible according to his ordinary schedule of meals and physical activities. When an organic lesion is suspected, and the diagnostician wishes deliberately to overlook the functional aspects of the case, the time required for the study may be greatly shortened by giving an opaque meal to be taken at bedtime and seeing the patient the following morning for a study of the cecum and proximal colon, the distal colon to be studied during subsequent hours, or one may commence with the barium enema. The colon may be studied after air distension, after an opaque meal or after an opaque enema. Each of these means will be briefly described.

Insufflation. For gas distension of the colon an ordinary rubber bulb is fastened to a tube which the patient is asked to

FIG. 8. Tracings showing three variations in the disposition of the pelvic loop. C, cecum. D, descending colon. S, pelvic loop. A, rectal ampulla. (After Schwarz.)

insert an inch or two into the rectum and, if necessary, hold there. Then, while the fluoroscopic screen is being observed, air is pumped in, visualizing very quickly and easily in order the pelvic colon, descending colon, splenic flexure, and on over to the cecum. The haustrated appearance of the colon is typical. The practical diagnostic worth of this procedure is limited, and its use confined to the differentiation of certain tumors or foreign bodies, or to set out more clearly the contours of some neighboring organ. The method is not without danger in some cases of stenosis, and is much less suitable for most purposes than filling the colon with opaque material.

Contrast Studies. The contrast material may be introduced into the colon either in connection with a meal or by an enema.

The writer recommends study of the colon following the meal as being more likely to give accurate information concerning the function of the bowel, reserving the injection of the opaque enema for those cases in which there is a question of gross obstruction (carcinoma, tumors, adhesions, etc.) and for testing the function of the ileocolic valve. Following the barium meal the studies of the colon

may be carried out at the eighth, twenty-fourth, thirty-second and forty-eighth hours, or at such other intervals as will best suit the program of the individual making the examination. An observation at the seventy-second hour is needed in many cases of diverticulitis. Other observations may be planned in special cases. Emphasis should be laid upon the advisability of generally adhering to a routine.

Opaque Meal. For the barium meal, any standard mixture with barium sulphate is acceptable. Formerly we employed a buttermilk suspension of barium sulphate. Rieder used a bread and milk mixture. At the present time there are a number of excellent preparations of barium sulphate ready for admixture with water and immediate use. Of course the opaque meal should be given on an empty stomach.

The following is Groedel's table relating to the passage of the opaque meal through the gastro-intestinal tract, giving the average time of the appearance of the shadow at the various points of the digestive canal:

| | Visible | Empty or Passed Beyond |
|--------------------------------------|----------------|---------------------------|
| Duodenum . | 5 minutes. | 2 to 4 hours. |
| Jejunum.. | 15 minutes. | 3 to 5 hours. |
| Ileum.. | 30 minutes. | 4 to 6 hours. |
| Cecum. | 2 to 3 hours. | 6 to 24 hours. |
| Right flexure | 4 to 6 hours. | |
| Left flexure.. | 4 to 12 hours. | |
| Rectal ampulla, at the latest.... | .. 24 hours. | |

Following a meal into which has been mixed 2 to 4 oz. of opaque material, the stomach should be empty within four and a half hours, at which observation the head of the barium column should have reached the cecum. The entire barium meal should have passed into the colon by the eighth, or at the most the tenth hour, when the head of the barium column should have reached at least as far as the middle of the transverse colon. The head of the barium column should reach the iliac colon from nine to sixteen hours following the ingestion of the meal, and the colon should be completely emptied

of the opaque material by the thirty-sixth to the forty-eighth hour.

Figures 9 and 10 illustrate the normal progress of an opaque meal through the alimentary tract.

Strict regularity in filling and emptying is not observed in the colon as it is in the stomach and it is difficult to fix any normal standard. Generally speaking, we may accept as a fact that within twelve hours after an opaque meal nearly all parts of the colon except the rectum should be visualized.

The appearance of the opaque meal in the colon is variegated. The haustra produce a segmentation of the colonic contents, most pronounced in the transverse but seen more or less throughout the large bowel. In the cecum the opaque masses form a cylindrical structure, usually with a rounded bottom, but varying greatly in the shadow pattern. The segmentation seen in the transverse colon gives the appearance of a festoon of leaves, likened by Schwartz (Fig. 11) to a figwreath; on other occasions they are separated from each other in a dumb-bell form. As we near the splenic flexure and in the descending colon boluses are more round and separated in a typical manner or crowded into a conglomerate mass. In the sigmoid definite masses begin to appear in coherent sausage-like forms, and in the rectal ampulla one sees the characteristic symmetrically formed mass.

For the *opaque enema* most radiologists prefer some modification of the method of Haenisch. The Haenisch enema consists of bolus alba 300 gm., bismuth carbonate 75 gm., and water sufficient to make 1 liter.

The writer for many years used the following formula: To 2½ dr. of gum tragacanth, add about 1 oz. of alcohol. Shake well. Add 20 oz. of warm water and shake. Add 3 oz. of barium sulphate, then 20 oz. of water shaking well each time. This mixture should be made up fresh shortly before using.

Holzknacht and Singer give the following formulae: (a) Barium sulphate clysma. To 1 l. of boiling water, a suspension of 2

a suspension of two tablespoonfuls of finest potato starch in a quarter of a liter of cold water is added. This is boiled

FIG. 9. Drawings from actual cases representing the average transit of opaque material through the bowel in healthy individuals.

soup-
spoonfuls of finest potato starch in three-fourths of a liter of cold water is added, and after being boiled again, 160 gm. of barium sulphate and ¼ l. of hot water is stirred with it. The mixture is then boiled for five minutes and cooled off to 112°F. This mixture can be preserved in the icebox for several days. (b) The bismuth clysma. To 1 l. of boiling water,

again for five minutes, and 120 gm. of bismuth carbonate stirred in three-fourths l. of cold water is added to it without boiling again.

Ordinary buttermilk, warmed to the temperature of 100°F., serves very well as a vehicle for the suspension of the barium for enema purposes. The latter preparation has the advantage of being

quickly prepared. There are various proprietary brands of barium sulphate on the market ready prepared for admixture with

of the injection varies with the importance of the segment to be explored. A liter usually suffices to reach the splenic flexure.

FIG. 10. Drawings from actual cases representing the average transit of opaque material through the bowel in healthy individuals.

hot water, so one need never be obliged to keep a patient waiting for lack of the materials for an opaque injection of the colon.

Jaugeas and Friedel recommended a paste, especially for the investigation of the rectum and sigmoid. Their paste consists of a mixture of vaseline and oil in equal parts, to which barium sulphate or bismuth carbonate is carefully incorporated in equal parts. This preparation can be injected with a syringe. The quantity

The technic observed during the injection of the opaque enema is not complicated. A preliminary cleansing enema given two or three hours before the opaque injection is usually advisable. Some radiologists prefer a mild laxative in place of the cleansing enema.

An ordinary enema container, with a capacity of 2 qts. and with 6 or 7 ft. of tubing attached, is suspended at a height of 2 or 3 ft. above the horizontal fluoroscope. At the middle of this tube should be

introduced an ordinary bulb syringe, with clamps upon the rubber tubing above and below this bulb. This syringe will be needed

come from below, illuminating a screen which lies upon the patient's abdomen or is supported above it. In this way the

FIG. 11. Characteristic shape of the opaque mass in various segments of the colon (after Schwarz). a, ascending colon and cecum. b, c, d, transverse colon. e, splenic flexure. f, pelvic colon. g, rectal ampulla.

to make sure that no air is introduced into the colon, to clear out the tube of sedimented barium from time to time, and to supply additional force for the injection should it be required. The enema tip is an ordinary glass tube about 3 in. in length, supplied by pharmacists for the purpose. Since glass is breakable, it is perhaps better to employ hard rubber or metallic enema tips. A supply of sterilized glass or other enema tips should be kept on hand, so there will be no delay in changing tubes for a series of examinations in quick succession. The writer ordinarily keeps in a jar of mild antiseptic solution a half-dozen enema tips each attached to a foot of rubber tubing ready fitted with a glass connector; at the close of one examination by opaque enema, it is only necessary to exchange the used enema tip and terminal foot of tubing for a fresh tip with its clean tubing, thus avoiding the necessity of renewing the entire enema equipment.

In having the barium enema administered, the patient lies supine upon the horizontal fluoroscope, so that the rays

progress of the injection can be watched as the fluid enters. The rectal point is inserted by the patient himself, but not more than an inch or an inch and a half. When a rubber tube is pushed up too high into the rectum it folds upon itself and sometimes kinks and prevents the entry of the injection. Furthermore it is unnecessary to use any form of tube intended for high insertion into the colon. The so-called high enema is easily given with the means above described, and with the patient lying flat on the back. It is quite unnecessary to use long colon tubes with prolonged and often painful, usually futile, attempts to insert it through the pelvic colon well into the descending colon, in order to give a high enema. The attempts to make a high insertion of a colon tube in the belief that it can and should be introduced into the proximal large bowel in by far the great majority of cases, result in failure to reach the high point desired and at the same time cause pronounced overdistension of the pelvic colon.

It is of fundamental importance that the injection of the opaque enema shall be

controlled by fluoroscopic observation. Failure to do so, as in the case illustrated herewith, may lead to serious error of inter-

the current only at the exact moment his eyes are intently focused upon the field to be studied; the current should

FIG. 12. Appearance of right half of colon, with incomplete filling by opaque enema. Wrong interpretation would have resulted from failure to note that the filling was incomplete. (See Fig. 11.)

pretation. Figure 12 shows the appearance of the right half of the colon when the filling was thought to be complete and the conclusion had been reached that the patient possessed an anomalous cecum with inversion. Figure 13 shows the cecum as it really existed, after fluoroscopic proof that the cecum had been completely filled. It is sometimes helpful to turn the patient on the right side for a few moments at the termination of the injection to make sure that the filling of the cecum is satisfactory.

As in all fluoroscopic work, no observations should be attempted until the eyes have been in the dark for a sufficient length of time, so that the enema tube in the rectum can be readily seen. At least ten minutes are required for this preparation of the eyes, and often longer. The observer uses the foot-switch to turn on

FIG. 13. (See Fig. 10.) Complete filling of the right half of the colon shown in the preceding illustration, correcting what would otherwise have been a wrong interpretation of inverted cecum.

not be allowed to illuminate the tube a second longer than required for the necessary observations. The stopcock is opened and the study begun. In normal cases there appears in the pelvis a pear-shaped shadow which gradually increases in size, showing the filling of the ampulla. The distention of the ampulla having been accomplished, the opaque fluid begins to seek an outlet into the pelvic colon. Whether or not we shall be able to see distinctly the pelvirectal junction and the last inch or two of the pelvic colon depends upon the location and disposition of this portion of the large bowel; according to its variable position the outlet from the ampulla appears sometimes toward the right, sometimes in the middle, and sometimes toward the left. When it appears toward the left it is usually possible to distinguish the pelvirectal angle very

well, especially if the patient be turned slightly so that oblique illumination can be employed. When it appears toward the

FIG. 14. Distention of the colon by air insufflation, to bring out and better identify the diverticula recognized by retained barium from a previous barium meal.

right or in the midline, the shadow of the opaque mass in the ampulla obscures the vision. In certain cases studies by means of stereoscopic films are exceedingly helpful.

It should be remembered that in almost every case, where the enema is injected with the patient in the supine position, there will appear to be a narrowing of the bowel where the pelvic loop passes the ilipectineal line at its junction with the iliac colon. The appearance of narrowing is often exaggerated by the very short mesocolon possessed by this segment of the large bowel, and especially by the adhesions which often exist at this point. There first appear in the van of the advancing column several relatively small boluses, showing the regular spacings due to the indentation of the haustra coli. Under the increasing pressure, however, these haustral markings are smoothed out and the

bowel shadow becomes broader, darker and homogeneous. The normal pelvic colon rises higher in the abdomen during the injection of the enema, owing to the increasing pressure. When the rise of the pelvic colon fails to occur, it may be taken as evidence strongly suggestive of adhesions binding it down.

After entering the pelvic colon, and particularly after passing the iliopelvic junction into the iliac colon, the progress of the opaque stream is uninterrupted. The enema usually flows quickly up the iliac and descending colon, where it follows a course backward over the iliac crest, upward and forward around the splenic flexure, forward and downward across the transverse colon to the hepatic flexure. There is normally the appearance of retardation of the opaque stream during its passage around the splenic flexure. This is only apparent, as will be appreciated very easily if the patient be examined in the supine position with a tube placed laterally, the screen being held vertically against the left side. Or, if the colon be studied stereoscopically, the two legs of the splenic loop (the last portion of the transverse and the first portion of the descending colon) are seen to be widely separated, the descending colon lying far dorsally to the last third of the transverse colon. The kinking which is supposed to occur often in the splenic flexure is rarely very sharp, but in those cases where it does occur the progress of the enema may be hastened by turning the patient upon the right side for a few moments. In the great majority of cases, however, it will not be necessary to turn the patient from the supine position in which the injection is started.

In the transverse colon it is sometimes observed that in the midline in front of the spine there is an apparent filling defect due to the saddling of the colon over the spinal column. This is especially noted in cases of increased intra-abdominal pressure.

In the hepatic region the fluid sometimes

is observed to follow a very devious course (Figs. 5, 12, 13), indicating a redundancy of the bowel at this point. Very rarely indeed is there any real kinking even when adhesions are numerous. Occasionally the fluid passes directly into the ascending colon, especially in well-nourished individuals; often it flows first upward in a direction parallel with the ascending and to its outer side, but later it returns and enters the ascending. Now the opaque fluid spreads rapidly, filling the ascending colon and the cecum, usually without difficulty. When the ileocolic valve is competent, the enema stops at the cecum; but in the rather large percentage of cases in which the valve is found insufficient, the terminal coils of ileum are seen to fill for a greater or less distance.

In brief résumé, it may be stated that the normal colon can be filled by injection within a few minutes, the patient reclining upon the back, without elevation of the pelvis or the use of the colon-tube. There are certain physiologic obstacles which can be overcome by waiting, by manipulation, and sometimes by change of position. The greatest expansion is noted in the ampulla and sometimes in the cecum. Excepting the ampulla, the caliber of the colon, thus filled by opaque enema, gradually increases from about 3 cm. in the pelvic colon to 6 cm. in the cecum. The larger the amount of the injection, the more redundant the colon, for it expands not only in breadth but also in length.

Normally, the opaque enema, which is perfectly bland and unirritating, proceeds through the entire colon to the cecum without exciting any visible peristaltic contractions; but in the conditions of inflammation or overdistention characteristic ring contractions may be excited. When seen, these have diagnostic value. Sometimes they may cause confusing pseudo-filling defects. Normally several minutes elapse without such peristaltic waves, even after the head of the enema column has reached the cecum. The

haustral markings which have been smoothed out during the entry of the enema, usually return after a little time,

FIG. 15. Chaoul's Balloon-Belt Compressor, for bringing out the details of the rugae or other mucosal markings in the stomach or colon.

occasionally in an instant, but usually more slowly, beginning first in the distal colon.

Following the study of the enema-filled colon, we often find it very instructive to watch the emptying of the enema or to study the colon immediately after the expulsion of the enema. Haenisch advises that the container from which the injection has been made be lowered, and the enema allowed to return by gravity. The emptying of the colon is thus watched under the screen. This is often very inconvenient, however, and most of the aid thus obtained can be secured by a screen study immediately after the patient has expelled the enema. It is of great importance that the roentgen installation for fluoroscopic work should be so arranged that at a moment's notice a film record may be made of any desired phase of the radiosopic appearance. This is especially needed during the study of the pelvic loop, for, if the making of this record be postponed until the entire colon is filled, the turning of the patient toward the left to secure the necessary obliquity of irradiation to show up the iliopelvic junction, may throw the shadow of the large cecum and often also that of the terminal ileum over the shadow of the rectal ampulla and lower sigmoid, thus causing a tangle

of shadows almost impossible to unravel. It is our custom to make 8 by 10 in. film records of the rectosigmoidal junction just as soon as it is visualized, without waiting for the head of the enema column to fill the descending colon; if we wait until the opaque column of injected fluid reaches the cecum, the shadows of the cecum and terminal ileum may overlap the shadows of the pelvic loop and obscure it, thus leaving a chance of overlooking important pathological changes. After the entire colon has been filled, a large film record should be made in the usual prone position; this and the smaller films made during the course of the injection provide a complete record of the colonic morphology which may be studied at leisure.

Recent publications have brought out several modifications of the ordinary barium enema which if expertly carried out seem to add points of value to the examination with the opaque injection. Fischer recommended the inflation of the colon with air after the introduction of the opaque material in as small a quantity as compatible with arrival of the head of the enema column at the cecum. The contrast secured by the inflation of the colon brings out more distinctly lesions visualized by the opaque mixture (Fig. 14).

H. H. Berg, H. Chaoul and others have published beautiful roentgenograms secured after making very strong local compression over the part of the bowel under suspicion either after an opaque meal or after an opaque clysma. The compression is secured by a belt-balloon device (Fig. 15), which is strapped about the patient's body, the patient placed in proper position on the radiographic table, and the compression made by pumping air into the balloon until the satisfactory degree of localized pressure

is secured. The relief-pictures obtained in this manner show with an extraordinary wealth of detail the appearance of the mucous lining of the alimentary tract, and permit the recognition of earlier lesions than is possible with the older irrigoscopic methods.

As above stated, in order to be thorough and to adhere to a routine, the writer prefers to examine the colon both by opaque enema and by opaque meal in every case. When the clinical evidence seems to indicate a colonic lesion of an organic nature, it is probably best to begin with the opaque clysma in order to avoid if possible filling the colon above an organic obstruction with opaque material. When the findings following the barium meal seem to point to obstruction in the colon at a certain point, testing the colon by opaque enema will give additional evidence of considerable value and serve as a reliable check upon the barium meal findings. Observation of the colon immediately after the expulsion of the opaque enema will still further control records already made.

The roentgen method, when carried out in the thorough way just outlined, in the hands of experienced radiologists will give findings which are nearly always correct. If an organic lesion obstructs, or if it is sufficiently large to produce symptoms, it ought not to be overlooked, and in a number of instances we should succeed in locating a tumor of the colon before it gives rise to symptoms.

In a subsequent issue of this journal, the writer will describe in detail our present knowledge of the motor function of the colon, and the importance of keeping in mind normal motor manifestations while interpreting roentgenograms of the colon.

BETTER PROTECTION IN VERTICAL FLUOROSCOPY*

J. BELOT, M.D.

PARIS, FRANCE

OF ALL radiological technical procedures screen examinations are the most dangerous; in fact, at present fluoroscopy is the only phase of radiological investigation or therapy in which it is almost impossible to secure efficient protection for the radiologist. It is true that with a modern, well-organized installation, radiography and radiotherapy no longer threaten with danger those who utilize them. In my own hospital the French Government has spared no expense to endow the newly installed radiological services with apparatus affording the necessary protection. It is to be hoped that the older laboratories may soon have their older equipment superseded with modern instruments; the lives of the radiological staff may depend on such a renovation of old equipment.

Fluoroscopy, on the other hand, especially in the upright position, presents grave dangers for the radiologist. These dangers are of three classes:

1. Danger of electrocution attending the use of the high tension current.
2. Danger from direct irradiation, that is, absorption by the fluoroscopist of some of the x-rays emanating from the tube, by placing his body or a part of it in the direct pathway of the active rays.
3. Danger from absorption of secondary rays emitted by the substances encountered by the direct x-rays. The body of the subject being examined constitutes the most important source of secondary radiation.

Under present day conditions of fluoroscopic work, electrocution is rare but possible; we are sadly aware of some tragic examples. Its infrequency is due more to the suppression of certain models of particularly dangerous generators than to the employment of safety devices which are still imperfect. One can never be sure of protection from accident should a high ten-

sion wire unfortunately become detached and come in contact with the radiologist by the intermediary of some metallic piece.

Protection against direction radiation is more easily secured. The manufacturers should be obliged to construct all radioscopic apparatus in such a way that the screen or its opaque mounting should always exceed in size the dimensions of the illuminated field. The apparatus at present in use do not satisfy this condition. Everyone knows that if he opens the diaphragm somewhat quickly the bundle of rays becomes larger than the screen and exposes the observer to radiation. This is a grave fault of construction against which too loud a protest is scarcely possible. Furthermore, the lead glass covering of the fluoroscopic screen should be of a satisfactory quality and thickness, and the mounting of the screen should not be defective, permitting a gap of several centimeters for free passage of the rays.

The secondary radiation emitted by the subject under examination and by all objects which surround him, is considerably more harmful. I have on numerous previous occasions called attention to this fault, and by careful observance of the skin damages suffered by various radiologists I have demonstrated the reality of the danger from secondary radiation.

I have recently announced the realization of an efficiently protected fluoroscope instrument for examination in the vertical position, the principle of which I shall set forth in subsequent paragraphs. The purpose of the instrument is to insure absolute protection for the radiologist and his assistants:

1. Against high tension current accidents (including unintentional contact with a high tension conductor.)
2. Against direct radiation originating in the x-ray tube.

* Submitted for publication March 20, 1930.

3. Against secondary radiation, of which the patient is the principal source. To accomplish this, I have divided the

opening of its door cuts off the primary current.

2. A dark room reserved for the radiol-

FIG. 1. Lateral view of Belot's safety upright fluoroscope.

installation of the vertical fluoroscope into three parts:

1. A separate cabinet which can be left lighted is strictly reserved for the generating apparatus and for the tube which produces the x-rays. No one has access to this place while it is dangerous, for the

FIG. 2. Rear view of Belot's safety vertical fluoroscope (rear panels of protective material removed for the photograph).

ogist and his assistants: This contains the screen and all the control apparatus.

3. Between these two chambers is a clear corridor, reserved for the patient, which he may enter easily under the guidance of a nurse who is herself protected.

The walls of each of these chambers are fitted with windows conveniently arranged to permit free passage of the useful bundle of x-rays necessary to illuminate the screen placed in front of the physician.

The chief difficulties of the problem grew out of the necessity of correlating the movements of the patient and of the tube, a control so necessary for fluoroscopic examination.

I first set myself the task of arranging to move the patient only, leaving the tube and the screen fixed and in proper relation to each other. But the construction of a platform permitting displacement of the patient in all directions was very complicated and costly. I may add that certain patients, especially injured patients, found it very difficult to tolerate the movements brought about in this manner.

So I gave up this idea for the following: The patient placed on a movable platform executes mechanically all lateral and rotating movements; the tube and the screen, invariably fixed in relation to each other, can be raised higher or lower, thus making unnecessary any movement of the patient in the vertical direction. It is possible with this device to direct the radiation through various obliquities.

Thus, upward displacements are assured by simultaneous movement of the tube and screen; the incidence of the rays is modified by the obliquity given to the useful bundle by inclining the tube; the patient is moved laterally by lateral movements of the platform on which he is placed; orientation is secured by rotating the platform. All these movements are necessarily brought about at a distance by electrical and mechanical devices under the control of the radiologist.

To the control of these movements must be added command of the size of the opening of the diaphragm, and of the anticathode-screen distance, to say nothing of the control of the electrical apparatus furnishing current to the tube.

From his place, without effort, the radiologist has under control of his left hand the height of the tube and screen. The movements of the patient, the opening and closure of the diaphragm by means of one hand, combined, simulate reflex movements.

This installation presents an absolute security for the radiologist and places the patient and the operator in safety

FIG. 3. Belot's safety vertical fluoroscope seen from the operator's side.

from all danger of electrocution. Furthermore, the patient who remains in the lighted corridor is not unfavorably influenced and his organism functions under normal physiological conditions. There is no difficulty in examining children with this apparatus. I may add that the cleaning and warming of this corridor are easy without imposing an excessive temperature on the radiologist or his aids.

Efficiently installed, this system permits rapid service for the successive and uninterrupted passage of patients, entering at one end of the corridor and leaving by the other. During the change of patients, the physician and his assistants remain in the obscure room, without spoiling their accommodation.

AN IMPROVED UTERINE RADIUM APPLICATOR*

HAROLD SWANBERG, M.D., F.A.C.P.

QUINCY, ILLINOIS

THE AUTHOR, sometime ago,¹ designed a radium uterine applicator, especially adapted to treating uterine

ual canal length, thereby irradiating the entire uterus.

3. Heavy filtration, greater in the vagi-

FIG. 1. Individual parts of the original applicator.

FIG. 2. Original applicator assembled for use in a uterine canal of average length.

malignancy in accordance with the technic of Regaud (Associate of Madame Curie), of the University of Paris. The principles involved in the use of the instrument are:

1. It permits irradiation to the entire uterine canal from multiple radium centers, one center supplying radiation in the vagina.

2. Adjustability. Uterine canals of different lengths can be easily radiated by assembling the applicator to fit the individ-

nal portion of the instrument than in the uterine part, thus protecting the sensitive vaginal mucosa, and minimizing the danger of formation of fistulas.

The original instrument, now known as Applicator No. 1, is constructed of 22 karat gold of special alloy (density 18.4) covered with aluminum. Filtration in the uterine portion is equivalent to 1.5 mm. of pure platinum and 3 mm. in the vaginal part. Gold is substituted for platinum (density 21.4), because of its almost equal density, and, because it costs only about one-fifth the value of

¹Swanberg, H. A new radium applicator for carcinoma of the cervix. *J. A. M. A.*, 90: 1289, 1928.

* Submitted for publication March 17, 1930.

platinum, lowers greatly the construction expense of the instrument.

Certain radium therapists questioned

has been reduced to 1.9 mm. This instrument necessitates, however, the use of small-sized radium needles in tandem

FIG. 3. Individual parts of applicator as now made. (Note but one end-piece and three sectional parts.)

the advisability of using such heavy filtration; hence an applicator of slightly lighter density and somewhat smaller dimensions was devised, known as Applicator No. 2. This applicator is also constructed of gold covered with aluminum. The filtration is equivalent to 1 mm. of pure platinum in the uterine portion and 1.5 mm. in the vaginal part. (This filtration is the same as that now employed by Regaud.)

In order to materially reduce the cost of the applicator, and still provide comparatively heavy filtration, a third instrument, designated as Applicator No. 3, has been devised. This is constructed of brass (density 8.4) instead of gold, and covered with aluminum. Applicator No. 3 has a filtration equivalent to that provided in Applicator No. 2, and it is approximately the equal, in outside dimensions, to Applicator No. 1. In order to keep the uterine portion of this instrument within practical dimensions, the central bore

FIG. 4. A. Uterine angle-wedge. B. Appearance of applicator with a 15° uterine angle-wedge in position.

arrangement. (The central bore of the uterine portion of Applicators No. 1 and No. 2 is 3.5 mm.)

FIG. 5. A. Uterine collar-button end. B. Appearance of applicator with uterine collar-button end in position to treat a short cervical canal.

A number of additional improvements in the applicator have been made.

This applicator was originally provided with three separate uterine end-pieces of variable size, and one short uterine

one uterine end-piece and there uterine sections of variable size.

Some gynecologists object to the use

FIG. 6. A. Uterine extension part (made in various lengths). B. Appearance of applicator with uterine extension parts assembled to treat an unusually long uterine canal.

section. Increased flexibility with decreased cost has been secured by providing but

FIG. 7. A. Screw-cap for uterine extension sections. B. Capsule made by screwing screw-cap on the uterine extension end.

of a long straight instrument in the uterus and contend that all such devised should be curved or so constructed as to more nearly conform to the direction of the uterine canal. This has been overcome by the construction of an angle-wedge, which can be attached to the applicator. Several types have been provided so

FIG. 8. A. Side view. B. End view. The double vaginal end for the applicator.

that angles of 10° , 15° or 20° are obtained in the uterus. We have also devised an adjustable uterine angle-wedge so that the direction of the angle, in relation to the vaginal cross-arm piece, can be quickly changed to any position.

Occasionally, it is necessary to use the applicator to radiate the stump of a cervix when a supravaginal hysterectomy

has been previously performed. The cervical canal in such cases is usually about 2.5 cm. long. This is accomplished by placing a small collar-button end to the short uterine portion of the applicator.

The uterine portion of the applicator can be indefinitely prolonged by using additional uterine extension-sections of various lengths. This permits thorough radiation to the entire uterine canal regardless its length in the individual case.

The various portions of the uterine section of the applicator can also be used as applicators elsewhere in the body. By the use of a separate screw cap, it is possible to convert a uterine extension section and end into a separate capsule of variable size, thus virtually converting the applicator into one of universal applicability.

The most recent improvement has been the provision of a double vaginal-end to the applicator. This permits the use of two radium centers in the vagina instead of one, and is highly desirable when the vaginal vault is large and the applicator used in conjunction with a colpostat.

It is also convenient when the vaginal vault is small and it is impossible to use a colpostat in addition to the applicator.

FIG. 9. Appearance of applicator with double vaginal end assembled for use in a uterine canal of average length.

THE IMPORTANCE OF UROGRAPHY IN THE INTERPRETATION OF ABDOMINAL SYMPTOMS*

CHARLES W. MOOTS, M.D., AND JAMES A. H. MAGOUN

TOLEDO, OHIO

WITH an ever-increasing frequency, the profession in general makes use of the urologist in attempts to solve the extremely difficult problems in diagnosis which present themselves, but there are yet too many cases submitted to operation without the merciful aid of this illuminating branch of medicine.

Fortunately, many of our ideas of specialism are rapidly changing. For instance, we can all remember the time when it was thought a specialist was some one who knew at least one thing well. Sad to relate, even this was often not true. Today, a real specialist must have a thorough knowledge of the functions of every organ in the body, and then have a familiar knowledge of all known technic to correlate the information possibly attainable concerning some particular organ or system of organs. The urologist, for example, should be well grounded in all matters of general medicine; a competent anatomist; thoroughly conversant with the physiology of all organs; be especially keen in the interpretation of circulatory symptoms, and finally, be particularly familiar with all possible pathology of the abdomen and pelvis. With the aid of the advice of this type of urologist, the general or abdominal surgeon should bring his errors down to the very minimum. There are quite a generous percentage of this assembly, who were compelled to make all their diagnostic decisions before the days of the benevolent aids that are now offered by laboratory technic and highly developed specialism. To say that our surgery in those days was "all poor surgery," would be quite as far from the truth as to say that "all surgery of today

is good surgery." However, that it is now possible to have these aids, the burden of this discussion is an effort to arouse a determination to more frequently make use of them.

The present high prominence of urology, and especially urography, has been gained by constant and rapid progress. If I may be allowed the personal allusion, it has all occurred in the professional life of myself and therefore, during that of many of the audience.

It was only as far back as 1897, that Tuffier probably first suggested the combination of an opaque ureteral catheter and radiography. In 1906, occurred the first successful outline of the ureter and renal pelvis in the roentgenogram, which was made possible by the injection of colloidal silver; gradual improvements in technic followed, which finally resulted in the use of the salts of the halogen group, by Cameron in 1918. These have stood the test of service during the past decade, and it is during these past ten years only that urography has been made available to the profession in general.

Time will not permit a lengthy consideration of the contraindications to urography, but in passing, it should be urged that this work should be carried out by a thoroughly competent urologist and that the roentgenographic apparatus be located in the cystoscopic room that the roentgenogram may be taken without delay following the catheterization and injection.

The advantages derived from a more or less routine urography are not alone confined to the prevention of unnecessary surgery to organs not diseased, but apprises us of unsuspected pathology in the kidneys

* Read at the forty-first annual meeting of the American Association of Obstetricians, Gynecologists and Abdominal Surgeons, Toronto, Ont., September 10-12, 1928.

and ureters, which will very frequently permit us to successfully attack that pathology and prevent destruction of kidney tissue. Chute of Boston published in 1924, "An Analysis of Fifty Cases of Renal Calculi" showing the importance of early diagnosis and treatment of this condition. The principles he advocated are well worthy of our careful consideration, for which purpose I must simply refer you to his valued paper.

Pathology of the urinary tract may be confused with that of practically every abdominal organ, but there are a few organs which are especially liable to receive too much attention and treatment if urography is not properly used.

First comes the so-called cases of *chronic appendicitis*. The frequency with which a perfectly normal appendix is removed with no relief of symptoms has been appalling. This mistake has occurred in my own experience even after a thorough gastrointestinal study by a supposedly competent roentgenologist. A properly taken pyelogram would have prevented this error as it would in many instances that occur only too frequently.

Acute Appendicitis. At first thought it might seem most improbable that confusion concerning this disease should ever occur. However, it has frequently been diagnosed and operation completed upon a perfectly normal appendix.

The gall bladder is an exceedingly fertile field for unfriendly and unscientific treatment. A flat roentgenogram followed by urography will often disclose a stone or stones in the right kidney or ureter, or an hydronephrosis. On the other hand, the symptoms may point strongly to renal calculi, as they did in one of our very recent cases, but urography proved the urinary tract free from pathology which might cause the symptoms, and a further study revealed the stones to be in the gall bladder.

Ptosis of kidney can positively be diagnosed and may thus save the patient several unnecessary operations.

Tumors of the right kidney are at times diagnosed as lesions of the liver, when urography would speedily and surely

FIG. 1. Case 1. Calculus right mid-ureter.

"dispel the doubt and reveal the truth." With somewhat less frequency, difficulty of diagnosis is encountered with acute-diverticulitis, lesions of the pancreas, twisted pedicle of ovarian tumor, retroperitoneal sarcoma, and malignancy of the large intestine. A complete urological study, together with the use of the sigmoidoscope and general Roentgenograms, will reduce our mistakes to a minimum. To illustrate my contentions, I will cite a few cases that have been studied in our clinic during the past year.

CASE 1. W. S. a colored male, admitted August 30, 1926, complaining of pain in right iliac region, and a history of similar attacks for past seven years. One year previous to admission, his appendix had been removed but the same symptoms persisted. Physical examination practically negative except for some pain upon heavy percussion over right kidney. Urine negative. Leucocytes, 14,640 with 74 per cent polymorphonuclears. Blood urea 17 mg per 100 c.c. of blood. Wassermann negative. A plain roentgenogram showed a shadow opposite the fourth lumbar vertebrae on the right side. Cystoscopic examination revealed a normal bladder. A No. 4 flute catheter was passed up the right ureter and a pyelogram was made. This showed the shadow found on the flat roentgenogram to be included in the ureterogram, and a diagnosis of right ureteral calculus was made. The patient strongly desired operation rather than manipulation and an urgent necessity for his return

to work with the briefest period of morbidity being also present, a ureterolithotomy was done through a muscle splitting incision and

urged the importance of study before surgery. It was two months before she was able to leave her home and come to the clinic. An

FIG. 2. Case II. Extra-renal shadows, right.

the patient discharged in excellent health and spirits twenty-one days after the operation, and has remained in perfect health.

CASE II. Mrs. B., aged thirty-eight, first seen at her home, 50 miles in the country. Her chief complaint was pain in the right side extending from the chest to vulva, following the course of the right ureter. These attacks usually lasted from a few days to a few weeks. She had the first attack twenty-one years ago. Ten years ago, had a cholecystostomy, but no stones found in the gall bladder. Thought she had some little relief for two years, though the attacks continued. Two years after the cholecystostomy, the attacks began to increase in both frequency and severity and when seen this last January was incapacitated more than half the time. The patient described the attacks as coming on with a sort of tired feeling in upper right abdomen, this was followed by severe pain which radiated to the back and then down to the vulva. Sometimes, but not always, there was nausea, never vomiting. There was invariably frequency of micturition with distress while voiding, the intervals between micturition being only twenty minutes. The case seemed easily one of renal calculi, but we

FIG. 3. Case III. Calculous upper left ureter.

urinalysis and blood study were negative, and it should be noted especially that a Vandenberg was negative. The icterus index was 8. Cystoscopic and phthalein tests revealed nothing of importance.

A plain roentgenogram revealed two ovoid shadows in the region of the right kidney, but a pyelogram showed these to be extrarenal. A gall bladder series was then run and a diagnosis of cholecystitis with at least two stones was easily made. Operation proved the diagnosis to be correct, one of the stones having a prolongation that extended down the cystic duct for at least half an inch. A cholecystectomy without drainage was done, and the patient left the hospital in sixteen days, quite well, and reported April 20 that she had remained so and was doing her own work.

CASE III. Mrs. C. aged thirty-seven, admitted to the Clinic, February 1, 1928. Chief complaints were frequent micturition, pelvic cramps, pain in back. This latter symptom had been present since she was two years old, and followed a fall down stairs at that time.

Following the routine studies, a plain roentgenogram was made which revealed a shadow just below the pelvis of the left kidney. It also showed that the patient had six lumbar vertebrae and that the right transverse process of the first lumbar was fractured. A pyelogram was then made which showed the shadow to be within the ureter.

Diagnosis: Calculi in left ureter just below

the pelvis of the kidney. Operation proved this to be correct. A ureterolithotomy was done and the patient is doing well.

Examination was negative, except for diffuse lower abdominal tenderness. No masses were palpable. Examination of the urine was nega-

FIG. 4. Case VI. Extra-renal shadow, right. Double pelvis, left.

FIG. 5. Case VIII. Stricture of lower left ureter

CASE IV. Male, aged forty-five, referred for gastric surgery. Chief complaint was distress in region of stomach.

A gastric study revealed some gastric hypertrophy with probably some adhesions about the pylorus. A gall bladder series was then made and a diagnosis of cholecystitis with stones confirmed. A study of the blood and urine was without important findings.

Bilateral pyelograms revealed the right kidney to have a double pelvis with double ureter for a distance of six inches where they united into one. Both double ureters were markedly dilated. Diagnosis: Hypertrophied stomach, cholecystitis with stones, right double pelvis with partial double ureters.

The patient was advised to make an effort to get along without treatment.

CASE V. M. D., Female thirty-six years old. Was admitted to the hospital September 27, 1927, complaining of pain across her lower abdomen. Six and a half years ago the patient states that her appendix was removed for this same pain. The pain is diffuse throughout the abdomen without radiation, and is not accompanied by any urinary, gastrointestinal, or menstrual difficulties, with the exception of severe constipation.

A left salpingo-oophorectomy was performed and examination of the tissue revealed a small cyst and chronic salpingitis. Following operation the patient gained in weight, but continued to have some pain in the abdomen, frequency, and many pus cells in the urine.

Cystoscopy revealed a bladder wall, inflamed diffusely to a grade 1. Both ureters were catheterized and bilateral pyelograms made. These revealed a horse-shoe kidney with a moderate amount of dilatation of the pelvis.

CASE VI. Female, B. F., forty-seven years old. First examined October 28, 1927, complaining of severe pain in the left lumbar area radiating over the crest of the ilium. This pain has been present for about four days. During this time, she has had frequency and burning on urination. There is no history of hematuria or tenesmus. There have been no other symptoms of importance.

Cystoscopy showed the bladder wall to be diffusely inflamed. Grade 1. Both ureteral openings appeared normal and a clear spurt was seen from the right ureter and a cloudy spurt from the left ureter.

Examination of the urine revealed an occasional hyaline and granulated cast. Pus 1. Cultures from both kidneys were negative

and urea concentration was 0.2 per cent. A flat plate revealed a shadow in the upper right abdomen. A right pyelogram showed this

FIG. 6. Case ix. Stricture of lower left ureter.

shadow to be extrarenal. A pyelogram of the left kidney showed a complete reduplication of the kidney pelvis and a markedly enlarged kidney..

CASE VII. Female, C. W., thirty-six years old. First examined October 13, 1927, complaining of pain in the right upper abdomen. The patient gave a history of having suffered with pain in the right abdomen and back for over three years. The pain does not radiate to the right shoulder but has extended toward the vulva. There was some tenderness in the region of the gall bladder and the right kidney was palpable and tender. No history of jaundice or gastrointestinal symptoms. She had had duodenal intubations for drainage of her gall bladder within the last year with apparently little relief. There were no urinary or menstrual symptoms. Examination of the urine revealed numerous pus cells but was otherwise negative. The blood chemistry was normal.

Cystoscopy revealed a normal bladder. Both ureters were catheterized and a right pyelogram was made. The pyelogram revealed a ptosis of the right kidney with a hydronephrosis of a Grade 1. No infection was present at the time of examination as all cultures were negative.

CASE VIII. Male, F. P. thirty-four years old. First seen January 30, 1928 complaining of pain in the left lumbar region radiating

toward the umbilicus. This pain had been present for three years. There had been slight burning on urination. Physical examination revealed small left varicocele and slight tenderness in the region of the left kidney.

Cystoscopy was negative except for the fact that it was impossible to pass any catheters up the left ureteral opening. On a second cystoscopy, five days later, a No. 4 catheter was passed up the left ureter with some difficulty. This was withdrawn and the tip of a Garceau catheter was inserted in the left ureteral opening and a left pyelogram made. The pyelogram showed a stricture low down in the ureter near the bladder wall. The middle calyx is indistinct probably due to lack of filling, although tuberculosis should be considered. Guinea pig inoculation was carried out and the ureter dilated to a No. 9 French. Dilatations are to be carried higher as this treatment relieves patient's symptoms.

CASE IX. Male, E. S., forty-nine years old. First seen July 26, 1927 complaining of burning on urination and pain in region of the sacrum. A posterior resection of the rectum was done two years ago. Since operation, the patient has had burning and pain on urination frequently and tenesmus with nocturia of a Grade 4. He has also complained of chills and fever and pain in the left abdomen.

Examination revealed some tenderness in the left lumbar area and a draining sinus in the sacral region and a left rectal colostomy. On attempting to pass a standard size cystoscope, considerable scar tissue was encountered in the posterior urethra. This was dilated with sounds to a No. 26 French. The bladder wall showed a difused degree of inflammatory reaction. Urinary spurts were seen to issue from both ureteral meati, and a No. 5 catheter passed easily up the right ureter. It was impossible to pass any form of catheter for more than 4 cm. up the left ureter. A pyelogram revealed marked stricture of the left ureter.

CASE X. L. M. female aged thirty, first admitted to the hospital complaining of abdominal discomfort and pain over sacral region. She has been subjected to the following operations within the past few years: appendectomy, cholecystectomy, incisional hernia and tonsillectomy. In spite of the surgery the patient still complained as formerly. Her symptoms had always been indefinite, but

there had been continued pain in right upper abdomen and back, and pain in lower right abdomen. She has suffered of nausea and vomiting and her bowels had been constipated. A pyelogram of the right kidney performed Feb. 6, 1928, reported pelvis normal with ureter dilated. A short interval after this, her gall bladder was removed and was reported by the pathologist to be of the strawberry type, and there were no stones. Her examination March 16, 1928 was negative with the exception of some tenderness in both lumbar regions and a difused tenderness through the

abdomen. The patient impressed one as having a large psychoneurotic element.

Cystoscopy revealed a mild degree of inflammation of the bladder especially about each ureteral orifice. Bilateral pyelogram revealed a hydronephrosis of the right kidney of a Grade III with considerable dilatation and tortuosity of the right ureter. The left pyelogram was practically normal. Cultures of both kidneys showed a colon bacillus. This patient has undoubtedly had a progressive pyelonephritis of both kidneys, more especially on the right accounting for many of her indefinite pains,

INFLAMMATION OF THE APPENDIX

ITS INFLUENCE ON THE PELVIC ORGANS AND THE VERTEBRAL COLUMN (PAIN IN THE SMALL OF THE BACK, LUMBO-SACRAL SYNDROME)*

DR. E. HÖNCK

HAMBURG, GERMANY

AS the following pages deal with the problem of pains in the small of the back (lumbago), it may be advisable to briefly indicate the meaning I attach to this term.

The general public frequently describe the whole region as far as the short ribs as the "small of the back," and in medical language the interpretation of the term is similarly vague.

I therefore wish to state that I only refer to those pains which are felt up to about the region of the ridges of the ilium and down to about the anal groove, whilst they may extend sideways about as far as the spot where the gluteal muscles connect with the hip bones.

The subject has occupied my attention for several decades.

In my larger work dealing with the part played by the nervus sympathicus in diseases of the appendix¹ I pointed out that patients suffering from diseases of the vermiform process often complain about pains in the small of the back and that a detailed examination of the rear portion of the abdominal wall and the back shows that the upper processes of the os sacrum are almost always subject to pain when exposed to pressure, and that the same remark applies also—though to a less extent—to the process of the fifth lumbar vertebra. This statement, however, was misleading; for in course of time it became evident to me (by means of x-ray) that it is precisely the spinous process of L₅ which is mainly subject to pain, whilst the same can only be said of the upper edge of the os sacrum in a more general and restricted way.

It is by no means easy to correctly determine the position of L₅ and its

process in the body of living persons; and so I trust that the mistake I made in looking for the L₅ process in too high a place will be considered pardonable.

Since then I have examined thousands and thousands of persons of both sexes, children as well as adults (in recent years mainly women) and I have over and over again found that my observation was correct. It is, indeed, a rare exception in connection with acute and chronic diseases of the appendix that the spinous process last referred to is not painful when exposed to pressure.

And always—almost without exception—my patients have stated that "it is there that the pain started."

According to their statements the pain radiates from there in both directions towards the region of the ridges of the ilium and also, frequently towards the righthand side only, beyond the ridge of the ilium into the region of the righthand groin and above Poupart's ligament.

If a careful examination is made by hand, it is found that the long dorsal muscles between the spinous processes and the ilium are painful. There one finds indurations and contractions of the kind already described by Cornelius, the latter being on the whole identical with the "geloses" described by Schade and with the "Hartspann" described by A. Müller-Gladbach.

The same observation is made in respect of the gluteal muscles, more particularly that part of them which is located below the ridges of the ilium and also that part located below the rear and upper spine of the ilium. In the case of elderly people it is not uncommon to discover fusiform indurations—for the most part in the

* Submitted for publication February 18, 1930.

plane of the lumbo-sacral connection—which may be exceedingly painful.

In a few cases I found some movable small glands close to the bone in the corners of the rhomboid fossa where not much adipose tissue has been developed. These are sometimes very painful, either on both sides or—less frequently—on one side only.

Erben is the only authority by whom anything similar is mentioned.²

Another spot sensitive to pressure—more especially in the case of sciatica and allied complaints—is located lower down, near the second point of intersection of a line divided into three parts and imagined to be drawn from the beginning of the anal groove to the trochanter major. It frequently happens that acute pains extending to the hinder part of the thigh and the outer part of the calf of the leg are produced by pressing that spot a little more firmly, such pressure being directed a little towards the interior. It is evident that, by doing so, the nerve trunks combined to form the large iliac nerve are pressed near the spot where they leave the pelvis and where they rest on the lower and hinder spine of the ilium.

If the palpation test is extended forward to the front part of the abdominal wall by way of the righthand ridge of the ilium (which is often very sensitive), the spots sensitive to pain which are characteristic of a diseased appendix may be discovered.

It should never be omitted to examine the patient whilst standing. In doing so, numerous tensions and indurations will be felt.

In a few cases I was able to ascertain the presence of a spindle resembling somewhat the stone of a date as regards its size and shape. It was almost as hard as a bone and was located near the forward and upper spine of the ilium and above Poupart's ligament.

If the patient is then made to double up her thighs and if the finger tips are inserted into the abdominal cavity (either

sideways or from above), it will be possible—provided that the patient is not too stout—to feel the ascending colon, the psoas and the curve of the vertebral column from the promontory upward about as far as the arches of the ribs. (It may be added in parenthesis that such palpation never causes any pain if the person examined is in normal health.)

The psoas is usually sensitive, either altogether or part of it. If the patient is made to lift her leg, the psoas is felt to become hard, and the sensitive spots become more painful than before. It is impossible to say whether the psoas itself, or the parietal part of the peritoneum, or the nerves located between the fibres of the muscle, or the ureter experience the painful sensation.

The large pelvis, too, must be palpated. If the finger tips are made to move back and forth on the colon so that it contracts, it will be found that, on its inner side and on the abutment of the large pelvis, the point of origin of the appendix is sensitive to pain.

In this connection it is necessary to bear in mind that the ureter is frequently affected in catarrhs of the right renal pelvis and that it is sensitive to pain.

Moreover, it often happens that the righthand side of the vertebral column up to its upper extremity is painful, either the whole of it or parts of it. The "κ" point, more especially, is conspicuous as a pressure spot located rather far down.

It is difficult to decide in each particular case whether the pain is located in the peritoneum, the mesenteric root, or the lymphatic glands and parts of the nervus sympathicus mixed up with it.

Radiations of the pain into the sensitive process of L.5, into the neighborhood of the stomach and the porta of the liver, and into the opposite side of the abdomen are likewise observed.

Very frequently pain is also caused by a deep-seated pressure on a spot just above the navel, when the finger tips reach the vertebral column. More than 20 years ago

I established a connection between this fact and the ganglion accumulations in that neighborhood, of which I showed at the same time that they must be sensitive to pain.

It is not the stomach which is the seat of the pain; because in the rare instances in which it is possible to palpate the "stomach fold" ("Magenstufe"), the latter is situated above the region where pain is felt. The pancreas cannot be concerned either; because it, too, is located higher. If the fingers move from this spot towards the left, pain is frequently caused near the sloping portion of the vertebrae, whilst there is less pain in the part lower down, towards the promontory. On the lefthand side, too, similar observations are occasionally made as on the righthand side—a fact which is presumably known to everyone engaged in such examinations. The circumstance that pain seated on the righthand side is sometimes also felt on the lefthand side, although to a less marked extent, may find its explanation in the principle of allochiria. Finally, it is necessary to examine the last of the lumbar vertebrae and parts at least of the entrance to the pelvis. The pain felt in the spinous process of L₅ originates in L₅ itself.

It is advisable to palpate the pelvic organs per rectum. The impression one is able to obtain in this way is far more accurate than that obtained through examination per vaginam.

In order to avoid tedious repetitions, I confine myself to stating that the results of this examination are in many instances identical with those reported by A. Müller-Gladbach. As a general rule, there is more pain on the righthand than on the lefthand side; but the results are subject to changes at different times.

It must also be borne in mind that the pelvic peritoneum (which reaches down to a considerable depth) and the numerous nerve elements cause a large part of the painful sensations felt in that region, and that the various uterine ligaments, the connective tissue enclosed by them, the

Fallopian tubes, the ovaries and the uterus itself are found in the most diversified conditions of swelling and displacement, more particularly so after repeated attacks of inflammation of the appendix.

I was much struck by an observation which I occasionally made when palpating the "bellies" of the musculus pyriformis which originate on both sides of the os sacrum.

This muscle was very sensitive to pain. The patient stated that she felt a violent pain, when it was lightly rubbed, on the thigh, just before the trochanter major; I made her abduct the right leg and caused her to draw it towards the resisting left hand. The muscle firmly contracted under the palpating finger, whilst at the same time a feeling of pain originated near the trochanter; probably at the spot where the muscle itself and its tendon join the bone. I feel disposed to look upon this phenomenon as something analogous to the pain felt in the knee which M. Lange³ believes to be caused by a diseased condition of the sartorius muscle.

I wish to add that an observation of the back frequently discloses the presence of some large or small furuncular scars in (and above) the "small of the back" and (with particular clearness in the case of elderly patients) of a network of distended veins extending right across the sacro-lumbar connection, but decreasing in size in both directions. The number of furuncular scars is less in the front part of the abdomen; the venous networks are frequently irregular, and occasionally the right side of the abdomen protrudes further than the left.

These, briefly, are (more or less completely) the results at which I arrived after carefully examining a large number of patients suffering from chronic appendicitis.

Although this is not the place for elaborate discussion along the lines of differential diagnosis, it is nevertheless necessary to make brief reference to the close relations existing between the appendix

and the pelvic organs, in order to explain the connection between the latter and the type of pains dealt with in this article.

I still adhere to the conviction to which I gave expression more than 20 years ago, viz., that the relations between a diseased appendix and the organs of the body, including, of course, the pelvic organs, are mainly brought about through the intermediary of the vascular nerves.

It has been known for a number of years that inflammations of the appendix exercise a permanently injurious effect upon the pelvic organs.

The first consequences of blood congestion in the pelvic organs caused by way of the nervus sympathicus are increased menses and other menstrual discharges.

In the speculum an increased quantity of clear mucus may be seen as being discharged by the cervix (the so-called catarrh of the cervix uteri). In some instances the vault of the vagina is redder than usual—an unmistakable sign of an engorgement affecting also the pelvic organs located higher up. The whole may be described as a *colpitis fornicis*.

In addition to this, my observations have absolutely convinced me that engorgements of the pelvic organs originating from the appendix by way of the nervus sympathicus cause the entire ligamentous apparatus of the uterus to become relaxed, so that in many instances the movable dorsal position of the uterus is the result of repeated inflammations of the vermiform process.

This connection was first described by Edebohls.⁴

Dorsal positions of the uterus fixed by scars have been known for a long time past to be the result of appendicitis (Douglas exudation).

If, owing to repeated congestions, a certain inflammation of the pelvic organs has become more or less chronic, it frequently happens that they become subject to disease quite independently. The direct cause may consist in the unsuitability of the measures adopted at the time of

the menses, in abortions, or in similar circumstances.

Once such diseases occur, the part of the appendix concerned may also become painful, *although the organ itself may not be inflamed at all*. In like manner, there may be an increase in the pressure pain felt by the L.5 vertebra.

This painfulness and even the spontaneous pain felt in the region of the appendix are obviously due to reflex congestion of blood caused by way of the nervus sympathicus, or else it may be that some formerly inflamed region whose stimulus threshold is lower feels sympathetic pain.

In my opinion, the condition of the appendix during pregnancy provides sufficient proof of this statement.

It is exceedingly frequent during pregnancy, even during the first few weeks, that the vermiform process is painful to pressure although the persons concerned may be quite ignorant of it. If they make any complaints at all, they refer to some pressure in the region of the stomach. An examination shows that they usually mean the above mentioned pressure pain in the part above the navel; and if the matter is further investigated, it is found that all the signs pointing to a diseased appendix are present, including the sensibility to pressure of the process of L.5. The temperature often rises from 37.6° to 38.0° or even a little higher than that. At that time there can be no question of a displacement of the large intestine described by Füh.

This condition is of such frequent occurrence and is so characteristic that any troubles of pregnancy that may exist are certainly augmented by it and may be partly connected with it. I have already drawn attention to this subject in my earlier publication.

Similar phenomena, but of a much more violent nature, take place in connection with tubal pregnancies, and may lead to grave errors of judgment.

It is well-known that tubal pregnancy is often due to changes caused by inflammations of the appendix. If, under

these circumstances, the foetus breaks up or a tubal abortion takes place, the peritoneum experiences a very violent and painful irritation, which also causes the region of the appendix to become very painful, not only in response to pressure, but also spontaneously, no matter whether the tubal pregnancy is located on the right or left side.

In a few instances of this kind I observed that a lefthand tubal pregnancy, shortly after its breaking-up, caused violent pains in the right shoulder, although no blood clots were found under the diaphragm when the operation took place. In these cases the region of the appendix was very sensitive to pain. The process itself, as seen during the operation, had undergone some pathological changes, but there was no acute inflammation.

I have already pointed out in my earlier publication that pains in the shoulder are of no infrequent occurrence in inflammations of the appendix.

When the region of the appendix becomes painful through sympathetic peritoneal irritation, renewed irritation is caused to the original course (whichever it may be), in which the stimulus threshold is permanently located at a low level. This accounts for the pains felt in the shoulder in cases of tubal pregnancy.

It will be evident from the preceding explanations that in many cases a differential diagnosis between an inflammation of the ovaries and the Fallopian tubes (right or left)—which is often characterized by similar symptoms, although these are less violent—and an inflammation of the appendix is almost impossible, except perhaps after prolonged observation and prolonged treatment.

The insufficient knowledge and the incorrect interpretation of these matters account for many a sin of omission committed in connection with displacement operations and similar proceedings.

In all these cases the process of L.5 may also become painful, and some of the secondary phenomena referred to above may also be present.

In no instance, however, have I found this pain and this sensitiveness to pressure in connection with inflammations of the pelvic organs when the appendix was in sound health, and when the process of L.5 was insensitive to pressure. If the process of L.5 is not painful, the region of the appendix as a rule, is also insensitive.

The inference I draw from this circumstance is that the changes that lie at the root of the painfulness of the process of L.5 are not directly caused by an inflammation of the pelvic organs.

According to my experience and my investigations it is beyond doubt that in the case of patients visiting a gynecologist one of the most frequent causes of the group of phenomena here described—although, as we shall see later on, not the sole cause—is a diseased appendix.

The complaint here referred to is of a typically chronic nature. Generally speaking, women of advanced age are more persistently attacked by it than younger women or girls; and in their case the symptoms are also more complete in every way.

Before we proceed to give an answer to the question as to the pathologico-anatomical changes causing the phenomena here described—the lumbo-sacral syndrome,—it may be useful to briefly outline the general course of the basic disease, i.e., appendicitis, and its bearing on the phenomena here described.

In this connection it is absolutely necessary to call to mind the fact that, as is proved by pathologico-anatomical investigations, a diseased appendix is of exceedingly frequent occurrence. It must suffice to refer to two authors only. Aschoff⁵ states that between 75 and 80 per cent of all persons between the ages of 50 and 60 suffer from a diseased appendix and that, at the age of about 40, only 1 out of every 3 persons has still a healthy vermiform process. In his latest publication on the subject, Aschoff points out that rudimentary acute irritations of the appendix occur far more frequently than is generally believed to be the case.⁶

Ribbert⁷ states that "more than 50 per cent of all persons above the age of 60 suffer from obliteration processes of the appendix." It should be borne in mind that obliteration processes are regularly an indication of serious or frequently repeated inflammations.

Inflammations of the appendix originating in childhood are characterized not only by pains in the abdomen, but also by painfulness of the process of L.5 caused by pressure and—occasionally—by pains in the "small of the back." Rectal examination shows that the pelvic peritoneum is also painful.

My experience has shown me that the danger is especially great to young girls at the time of their first menstruation. The pains incurred at that age are often wrongly interpreted. They are looked upon as part of their puberty development or as being connected with their "growth;" and no particular attention is paid to them.

I feel pretty certain that acute inflammation of the appendix is particularly frequent during those years. This opinion of mine, like most of the experiences here described, was already recorded by me more than 20 years ago in the publication repeatedly referred to. H. Kümmell holds the same view.⁸

It should therefore be emphasized that any pains during the years of "development" and at the first appearance of the menses always indicate some pathological condition which it is our duty to elucidate and which is often due to a diseased appendix, apart from constitutional and other causes.

The acute inflammations of the appendix which are observable at the first appearance of the menses usually take place after the discharge of blood is over.

The week succeeding the completion of menstruation is the time during which acute appendicitis is incurred by young girls and women.

In the medical reports on older girls and women suffering from a diseased appendix we frequently find statements to the effect

that the menses were not accompanied by any pain during the first few years, but that the opposite remark holds good for subsequent years, this being due not only to nervous conditions generally, and to developmental disturbances, but also to repeated inflammations of the appendix.

This assumption is supported by the fact that the region of the appendix is not infrequently the seat of the dysmenorrhoeic pain.

The effect of pregnancy on an appendix that had been inflamed has already been discussed in the earlier part of this article. Additional injuries are sometimes incurred by such women at the time of their confinement.

We are therefore justified in stating that these patients have been suffering for a long time from a diseased appendix and that the effects resulting from this diseased condition continue to make themselves felt throughout the patients' life. It is easy to understand why this should be the case, inasmuch as the diseased organ is directly adjacent to the L.5 vertebra and its connections, which are therefore exposed to permanent or frequently recurring injuries of the kind described by O. Schäfer in two cases (*Gynäkologenkongress*, 1907). In both instances there was an incipient acute inflammation of the appendix as well as an oedema of the right ileo-sacral fossa, the abdominal walls and the right appendages.

Although I had been convinced for a number of years that the painfulness of L.5 (which is almost invariably encountered) must be caused by certain definite changes undergone by the vertebra, I never succeeded in ascertaining the nature of these changes, not even by the occasional recourse to x-rays.

Moreover, I was of the opinion that it is not only the vertebra itself which must have suffered some injury, but that the same also holds good for its articular connections, the networks of the nervus sympathicus covering it and adjoining it,

the connective tissue surrounding the nerves, the ligamentous apparatus, the interarticular cartilage connecting L.5 and

A short time ago Hans Albrecht published a detailed report on the importance of these joints and their pathological

FIG. 1.

the os sacrum, and perhaps also for the hard membrane of the spinal cord or for the spinal cord itself. The latter assumption seems to me to be borne out by the observation that, if pressure is applied to the process of L.5, the resulting pain is sometimes felt as far away as in the upper parts of the spinal column and in the back part of the neck, this being a well-known indication of what Hegar formerly called lumbar cord symptoms ("Lendenmarksymptome").

Of similar occurrence are injuries to the ileo-sacral joints and to their ligamentous apparatus accompanied by symptoms which to some extent are identical with or supplementary to those observed by me.

I wish to add that, on the whole, clear indications of diseased ileo-sacral joints were comparatively rarely ascertained by me.

FIG. 2.

changes⁹ a report in which due attention is paid to the German and non-German literature on this subject.

Goljanitzki's paper entitled "*Die gewerblichen Erkrankungen des Kreuzbein-Lendenabschnitts und ihre chirurgische Behandlung*"¹⁰ proved exceedingly useful to me in connection with the interpretation of the symptoms observed by me. Even though his investigations apply to persons engaged in heavy manual work who had suffered some accident, there is so much resemblance between his observations and my own that I have thought it indispensable to take recourse to x-rays of the cases investigated by me. The very first x-ray shows some special difference.

DISCUSSION OF ILLUSTRATIONS

In order, however, to effect a comparison, I first reproduce a view (Fig. 1) showing a normal lumbo-sacral connection, seen sideways.

Figure 1. The intervertebral cartilage between L.5 and the os sacrum is seen to be uniformly developed. The lower and hinder corner of L.5 coincides with the hinder corner of the os sacrum; and the lower front corner of L.5 does not extend beyond the os sacrum either.

Figure 2. This photograph was taken of an 18-year-old girl employed as an office clerk whose appendix had been removed was impossible to account for the increased temperature in any way. An examination of the genital organs per rectum showed

FIG. 3.

3 years previous, since which she had suffered pains in the back. She was pale and—owing to the pains—very run down and emaciated. On the sagittal photograph the upper arch of the os sacrum shows a gap into which the shadow of the process of L.5 protrudes. On the righthand side this process adjoins the os sacrum; but on the lefthand side there is a gap between the two bones.

A remarkable circumstance was that the patient did not suffer any pain when she bent her body to the right and that she did suffer pain when she bent it to the left. It is evident that the gap shown in the photograph left a sufficient space for play whenever she bent her body to the right. Patient's temperature was continually slightly in excess of the normal. She had been under treatment for her lungs for a considerable time past. Nothing abnormal, however, could be discovered; and it

nothing abnormal, except for some pain in the pelvic muscles. Patient was virgo intacta.

The side view did not come off very well and is not suitable for reproduction. Dr. Lorenz states that "the process of L.5 rises very steeply and it is adjacent to the os sacrum."

Goljanitzki reproduces one photograph which is almost identical with it (patient suffering from accident). He chiseled off the process of L.5 and ascertained that the os sacrum was so soft it could be abraded without any trouble.

Goljanitzki therefore treats it as a case of "osteitis dissecans" and thinks that the process of L.5 bored its way, as it were, into the os sacrum (accident). Seeing that this patient did not incur any kind of accident, we are probably concerned with a case of spina bifida. The process of L.5 grew into the gap and caused, of course, a consider-

able amount of pain, chiefly in the back and on the righthand side of the abdomen. Patient is one of those persons who assert

nearly down to the pelvis; characteristic skin folds.

Internal examination: Uterus same as

FIG 4A.

FIG 4B.

their discomforts have increased after the operation for appendicitis.

I suggested to patient that, following Goljanitzki's example, the process of L.5 should be removed; but she refused. I do not know what became of her; but I do not think that the pain can be eliminated in any other way.

Figure 3. Mrs. K., aged about 35. Three children. Diseased appendix, but not operated on. Complains of always feeling a pain in the small of the back. The photograph shows a typical "sliding" vertebra.

Figures 4a and 4b. Mrs. F., about 30 years old. Two children. Complained of violent pains during her last pregnancy three years ago. Menses failed twice; unbearable pain in the small of the back and lower down in the abdomen.

Examination showed that patient was somewhat emaciated. Inclination of pelvis very slight; costal arch had prolapsed

during second or third month of pregnancy; appendages and whole lining of small pelvis somewhat painful. Promontory just accessible, projected distinctly in a downward direction beyond interior surface of os sacrum, painful. No organic changes apart from those mentioned.

External examination: All the typical features of lumbo-sacral syndrome were very pronounced; lower parts of the appendix region distinctly painful.

Patient stated that she was suffering from appendicitis several years ago.

Diagnosis: Spondylolisthesis in addition to pregnancy and chronic appendicitis. Temperature slightly above normal.

Fig. 4a. The x-ray photograph (side view) clearly shows the type of an L.5 that had slid forward. Intervertebral disk not noticeable.

Fig. 4b. The front view shows that the shadow of L.5 projects beyond that of

the os sacrum like a segment. The vertebra has probably moved a little towards the left. Hence, the upper lumbar vertebrae have been twisted towards the right, as may be seen from the fact that their processes project very far in that direction. Pronounced lordosis of lumbar part of vertebral column.

It is impossible to be sure in this case whether the advanced spondylolisthesis was mainly due to appendicitis or pregnancy. Subsequent investigations must settle this point. It is certain, however, that the lumbo-sacral syndrome was very pronounced. Patient had a miscarriage and discontinued the treatment.

Figure 5a. B. O., aged about 35, seen early in April, 1928. Two children, again pregnant (second or third month). Very violent pains in the small back and abdomen. Healthy woman of good constitution.

External examination: The abdomen, which is somewhat protruding, can be made to recede considerably upon pressure. Vertebral column and adjacent parts on left side almost insensitive; but righthand side exceedingly sensitive to pain, more especially L.5 and promontory. Caecum above entrance to pelvis very sensitive on inner side; a slight pressure there causes pain to spread to back, where process of L.5 and upper ridge of os sacrum are very painful on pressure. The same applies to connecting parts of long dorsal muscles between ilium and vertebral column and to upper gluteal muscles.

Urine: nothing abnormal; other organs likewise.

Internal examination: Uterus pregnant in the second month, is located fairly deep and backward. Appendages and Douglas's pouch sensitive. No swellings anywhere. Temperature (rectum) at first fairly stationary between 37.3 and 38.1 for many weeks, subsequently receding in consequence of dieting and proper care of bowels. Pains in the small back increased during observation, which lasted several months.

The x-ray shows that the hinder corner

of upper surface of os sacrum opposite hinder corner of L.5 projects about $\frac{1}{2}$ or 1 cm. too far forward, and that the intervertebral disk is narrow in that neighborhood, whilst it assumes a more or less cuneiform shape further in front. The space between the front corner of os sacrum and the corresponding part of L.5 is very large; but the frontal os sacrum does not project far beyond the front edge of L.5.

The process of L.5 is very wide. Its lower edge touches the upper edge of the first process of the os sacrum, which is also very well developed.

Figure 5b. A frontal view shows that there is sufficient room between the upper processes, but that the shadow of the process of the os sacrum touches that of L.5 and that the process of L.5 is curved towards the left and that it touches the process of the os sacrum without any intervening space.

Clinically, patient doubtless suffers from appendicitis during her pregnancy (fever and palpation tests). In addition, however, it may be surmised that the pain she feels in the back may be caused by the abnormal position of the os sacrum and the resulting friction of the two processes (cf. Goljanitzki). It was impossible for her to move backward. Any kind of movement caused her to be in pain, and there was no alleviation of it when she rested. Getting up in the mornings became a torture to her. Clinically, nothing abnormal was found in the ileo-sacral joints, although it might be suspected that the abnormal position of the os sacrum would lead to a wrong distribution of weight and that this would cause pain in these joints.

Patient declined to be operated for appendicitis, because I could not promise her that the pain in the back would disappear unless the process of the os sacrum were got rid off at the same time. Even then the result would not be certain, owing to patient being pregnant. Perhaps it might have been advisable to interrupt pregnancy at an earlier date. After a few months patient ceased to be treated by me.

Figure 6. Mrs. R., aged about 32, of slight, but even build. Normal weight 49 kilos. Resembles in her appearance a

the sensitiveness of the L.5 process remained; occasionally there was some fever, vomiting, etc., in the evenings. The opera-

FIG. 5A.

FIG. 5B.

14-year-old girl, but has given birth to 2 fine children under normal conditions. Complains of pain in the back. For a time her temperature went up to about 39.0° . Two years ago, when treating her for a so-called catarrh of the cervix uteri, (unspecified), I told her that her appendix was diseased.

The examination disclosed, externally, all the symptoms typical of an inflamed vermiform process. Internally, however, nothing abnormal was discovered, except that the appendages on the right were slightly sensitive, without enabling any differentiation to be made. I suggested an operation. After fluctuations extending for weeks, the pain in the back disappeared;

tion disclosed that the vermiform process was 10 cm. long and that it protruded into the right pelvis. Behind a stenosis at the distal end there was some pus. No deformities. Since then all the trouble has come to an end.

The sagittal view shows that the L.5 process and that of the os sacrum are contiguous.

A side view shows that the upper os sacrum is narrow and rounded and that it adjoins the lower surface of the L.5 after the manner of a condyle. The os sacrum almost looks like an infantile formation.

Patient, when doing gymnastic exercises, could easily describe a complete curve

backwards. I feel convinced that she would considerably suffer from pain in the back if she had to do heavy physical work, such

more or less solid connection of a fibrous nature.

If we recall to mind the results arrived at

FIG. 6.

FIG. 7.

as carrying loads and lifting them. Her light weight is very helpful to her.

What, we may ask, is the relation between the above-described irregularities at the connection of the lumbar vertebrae and the os sacrum and the spondylolisthesis on the one hand and the inflammation of the vermiform process—which is or has been present in all these cases—on the other?

Is it possible that repeated inflammations of the appendix can cause the last of the lumbar vertebrae to “slide downward,” provided that the irregularity in the development of the centre of ossification in the interarticular part of the vertebral arch (described by F. L. Neugebauer) is present?

I wish to point out that this irregularity does not imply the ossification of the vertebral arch, but merely results in a

by O. Schafer (to which reference has been made above), more especially the oedematous saturation of the whole neighborhood of the appendix after an acute inflammation of the latter, we feel convinced that the neighboring parts of the vertebral column must also have undergone the same changes in all their constituent elements, more particularly those parts where the vertebral column is subjected to the heaviest loads and where every movement of the upper part of the body leaves its principal effects.

The inevitable result is that the weak part (i.e., the fibrous connection of the interarticular portion) becomes loosened. In like manner, the intervertebral disk (and the ligamentous apparatus)—although free from vascular organs—is bound to receive a large amount of infiltration from the outside margin and to

become softer. The necessary consequence will be that the last lumbar vertebra starts "sliding downward."

In my opinion the preceding argumentation and the inferences drawn therefrom are obligatory and do not admit of any counter-arguments.

The same remarks hold good whenever the L.5 vertebra starts "sliding" owing to one or more pregnancies, not to mention the additional load resting on it. *If both causes are present in combination, the results must be more pronounced still.*

If the irregular development to which the spondylolisthesis is due is not present, the os sacrum (Figs. 5a & 5b) owing to the loosening of the ligaments and the intervertebral disk—may itself start "sliding forward." I believe that this hypothesis explains the peculiar way in which the os sacrum is partly covered by the L.5 vertebra (*sacrolisthesis*).

I would like to emphasize that obstructions to and disturbances of the development may play a certain part in this connection. This assumption seems to be borne out by Figures 6 and 7.

These figures show that the upper surface of the os sacrum is rounded in a peculiar fashion. This may possibly be accounted for by assuming that the os sacrum was functionally "sliding" on the lower surface of L.5 for a considerable period of time.

These matters, however, will have to be further investigated and elucidated.

As far as I am concerned, I wish to state—with all the emphasis resulting from decades of experience and study of this subject—that I consider appendicitis to exercise a predominating influence on the origin of the lumbosacral syndrome.

The x-rays do not always visibly show the alterations that have taken place in the articulation of bones and joints.

When conditions are favorable, disturbances in the development need not by themselves lead to discomforts and pain.

My experience, however, has also shown me that repeated inflammations of the

appendix not only exercise the adverse effects upon the connection of the lumbar vertebrae and the os sacrum (already described), but that they may also lead to serious disturbances of the blood circulation (by way of the vascular nerves, *nervus sympathicus*) in the upper parts of the vertebral column. The nature of these disturbances has been disclosed by the careful investigations carried on by Ricker and his pupils. There can, moreover, be scarcely any doubt that Sudeck's bony atrophy is also among the resulting consequences.

It is therefore quite in harmony with the views put forward by Sudeck when I state it as my opinion that the lumbar section of the vertebral column may be subjected to a certain amount of atrophy due to some inflammation in any adjoining region (i.e., an inflammation of the vermiform process).

In the further course of development the lumbar part of the vertebral column, affected by the load on it and the muscular action concerned, is bound to suffer some sort of deformation which, in turn, causes secondary modifications to the thoracic part of the spine.

Hence, there are numerous cases of curvature of the vertebral column in which the deformation of its lumbar section must be regarded as primary.

The case illustrated by Figure 7 is such that, in view of the kind of the deformity and on considerations of anamnesis—it must be regarded as a primary kyphosis of the lumbar section of the spine due to an inflammation of the vermiform process.

Figure 7. J. M., a slim, pale-looking, delicate girl of 21. In her 12th year confined to bed for a long time owing to pains in the back and abdomen. Shortly afterward first menses. Two years ago operated for appendicitis. Kyphosis of lumbar part of vertebral column, the apex of it being located in L.1.

Employed as an office clerk.

The x-ray is reminiscent of Figure 6. Here, too, the os sacrum is conspicuous

for its small size. Its hinder corner is rounded and is not coincident with the hinder and lower corner of L.5. Nevertheless, the front corner of the os sacrum projects a little. Interarticular cartilage wide, cuneiform. L.5 appears to have become somewhat detached from L.4 and to have slid a little forward; and L.4 appears to be pivoted about its front edge a little towards the back edge, so that higher up kyphosis was bound to develop by way of equalizing.

Presumably there was an inflammation of the vermiform process at the age of 12, and this was followed up by the modifications of the spine.

These relations have been known to me for many years; because I observed more than once in the case of young girls after recovering from acute inflammations of the vermiform process that convex scoliosis of the lumbar section of the spine set in on the left side after the lapse of a certain period of time. This led me to believe that Sudeck's atrophy of neighboring parts of the spine was the indirect cause of it.

Several years ago I tried to convince the medical world that this belief of mine was correct; but I met with no success, because I had no x-rays for evidence.

Since then I have added further observations; and I am now more firmly convinced than ever that my interpretation of the facts is the right one. That these serious effects of an inflammation of the vermiform process upon the spine have remained unnoticed for so long a time, is presumably attributable to the fact that several months may elapse before the phenomena become manifest and to the further fact that these effects make themselves felt even if the inflammation of the appendix has not been of a very serious nature.

Since then I have seen that, after inflammations of the appendix which were clinically of a very harmless character, curvatures of the spine developed. It was only owing to the fact that my attention was constantly directed towards these

matters and that, accordingly, my eyes were open to see them, that I was able to appreciate the cause of these curvatures. I had trained myself to disclose the group of lumbosacral symptoms and to understand the causes to which they were due.

If it is thought unlikely that disorders which are clinically so harmless that they only lead to vague discomforts and that they do not even necessitate a rest in bed can cause such serious deformations of the vertebral column, it should be borne in mind that we are here concerned with youthful persons whose spine is still in process of growing and that its growth, owing to the abundant supply of the vertebrae with nerves and vessels, may be easily disturbed locally, e.g., by disturbances of the blood circulation after the manner of what Ricker¹¹ calls the "peristatic condition," which may possibly also be the cause of Sudeck's atrophy (perhaps after serious inflammations lasting a considerable time).

I wish to point out that, as early as about a quarter of a century ago, I showed that disturbances in the blood circulation—caused by the nerves of the blood vessels—often make themselves felt in parts located a long way distant from the source; but this is not the place to go into these details again.

Let us also remember that in all inflammations of the appendix the pre-vertebral ganglions (gangl. coeliac.) above the navel are invariably the seat of sensitiveness to pain, and often that of actual pain.

All the elements contributing towards the formation of these ganglia, including the splanchnic nerves, are bound to become irritated. As the splanchnic nerves, by way of the spinal cord, are connected with the ganglia of the funiculus marginalis of the middle part of the thoracic section of the vertebral column, they, in their turn, are bound to affect the vessels of the thoracic wall—including those of the vertebral column—which originate there.

Hence, it may happen that an acute inflammation of the appendix may lead

to disturbances in the blood circulation in the thoracic part of the vertebral column and that these disturbances may cause that part of the spine to become less rigid, so that it may become deformed and that a secondary curvature is the result. It is not difficult to imagine that such a combination of near and far effects may bring about the most diversified modifications in the structure of the vertebral column.

It stands to reason that individual vertebrae (intervertebral disks) may also become subject to such modifications. This must depend on the anatomical condition present in each case. *It is equally obvious that any kind of inflammation of a part immediately adjacent to the vertebral column (and not only inflammations of the vermiform process) may tend to bring about the same results, although I feel disposed to believe that inflammations of the vermiform process occupy a special position in this respect, this being due to the fact that the vermiform process is located so very close to that part of the vertebral column which is subjected to the heaviest strains and to the further fact that the pre-vertebral ganglia can always be proved to be in a state of irritation.*

In this connection I cannot refrain from directing attention to a paper written by my teacher Rüdinger which even now is well worth reading.¹² I quote the following passage from it: "I do not know any part of the animal body supplied

with as large a number of nerves as the various sections of the vertebral canal." I wish to add that the supply of blood vessels is equally abundant.

By advancing the views outlined in this article I continue to proceed along the road which, almost 25 years ago, I started independently and from which I have no reason to deviate now, more particularly now since Ricker published the comprehensive and detailed results of his investigations (however keenly these may be converted) and—quite recently—since E. F. Müller, although proceeding by quite different methods, arrived at very much the same conclusions as I.¹³

It is certainly absolutely necessary that these matters should be carefully examined by others, not only because of their great practical importance or for the reason that they are indubitably connected with pathological and physiological processes that cannot be contradicted, but also because their investigation implies the application of new methods to the scientific problems with which we have to deal.

I hope to be able soon to publish a separate paper devoted to the conclusions to be drawn from the preceding material.

The x-rays originated partly in the laboratory of the Hamburg Sick Insurance Society (Dr. Lohfeld) and partly in the Institute conducted by Professor Holthusen and Dr. Lorenz. I desire to sincerely thank these gentlemen for the loan of the photographs.

The American Journal of Surgery is truly independent and enters into no "entangling alliances." It publishes many papers that were read before the leading surgical societies of the Country, but, it is *not* the "the official organ" of any organization. Every manuscript is selected by the editors, as worthy of publication—nothing is published merely because "it was read at the meeting."

EDITORIALS

AN INQUIRY INTO THE CASE FOR CHRONIC APPENDICITIS

ACUTE appendicitis is a surgical disease, the remedy for which is prompt operation, and the fact that it still exhibits an appalling mortality is a reflection upon our performance, or rather upon our delay in performance, not upon our therapeutics. The status of chronic appendicitis, however, is quite different. Surgeons and pathologists of equal skill and experience argue with considerable acerbity for and against its very existence, though the majority of surgeons continue to operate for it. The laity, almost in the same breath, demand that their appendices be removed and rail against the profession for taking them at their word and performing unnecessary surgery upon them. The result is hopeless confusion of thought

and action, and it is with the idea of clarifying in some small degree a subject so obviously in need of elucidation that I am venturing to ask you to consider with me a theme which some may think has already been considered too often.

Acute appendicitis is an established clinical entity; of that there can be no doubt. Likewise there can be no doubt that there is a type of appendiceal disease characterized by repeated acute exacerbations of more or less severity, from which the patient recovers and in which there can be elicited all or part of the syndrome of the acute disease. The patients who have passed through attacks of this kind and who, thanks to a skilled physician or a beneficent Providence or both, as

you will, have not perished in them, frequently have some residual evidence of the experience they have undergone. In some instances (I quote freely from Hertzler, whose masterly article on this subject anticipates all that I shall try to say to you) there is practically a complete return to normal. If only the fixed tissue cells are irritated, the exudate is quickly absorbed and restoration quickly occurs. A moderate degree of polynuclear infiltration may regress and leave no obvious changes. But parenchymatous tissue, once actually destroyed, is not replaced in kind, and some degree of scarring is bound to result. Indeed, the process may go on to total destruction of the organ and, if the patient survives, which is not the usual outcome of the untreated case, only the mesoappendix may be left as an evidence of what has occurred. But a scarred appendix is not necessarily the seat of present symptoms, and the changes we have described are evidence of past disease. They do not represent a continuing process. They represent a process which has occurred, which may occur again and which warrants surgery as a prophylactic measure because of that possibility. The correct nomenclature, however, for such a condition as this is recurrent or relapsing appendicitis. It is not chronic appendicitis.

With the conception of appendicitis as a recurrent or relapsing disease there can be no basis of quarrel. Diagnosis is self-evident, surgery has a logical foundation and end-results are excellent. The error is that we are thinking loosely and speaking with corresponding looseness. Hertzler is not the only one who has pointed out that the term chronic, as applied to a process extending over a period of time, is sensible speech, whereas the term applied to a degree of inflammatory reaction makes no sense at all. I plead guilty to this sort of slovenliness myself. I have no doubt that within the week I shall emerge from the operating room and request the stenographer to

put me on record as having removed a chronic appendix, when in reality I mean that I have removed an appendix which has been the site of inflammation in the past and which I fear may give rise to trouble in the future. Most of us, I think, are honorable in our endeavors and reasonably lucid in our ratiocinations. But we are also inclined to carelessness in the expression of our thoughts and our performances.

There is another type of appendicitis, however, which has no such definite etiology. It is the type manifested primarily by pain in the right iliac fossa, secondarily by vague digestive disturbances, the so-called appendiceal dyspepsia. It is the type of appendicitis which is the happy hunting ground of the occasional operator, and which is the despair of earnest clinical surgeons and equally earnest pathologists. For its mere existence is open to decided doubt. Conscience may make cowards of us all, but that sort of chronic appendicitis seems to make cynics of us all. Hertzler, who came up through the laboratory, puts it rather neatly. Who wants, he says, to report an appendix negative when the chief of the department of surgery has removed it on the ground that it shows chronic changes? The pathologist knows what he is supposed to find in such circumstances: either the changes in question or a new job.

The poor pathologist, as a matter of fact, is rather to be pitied. He does not know, any more than you or I know, what constitutes a normal appendix. One authority makes size, contour and location his norm. Another has an elaborate set of specifications as to histology. A third takes as his standard the appendix in infants from four to twelve months, which seems rather hard on the vast majority of adults, who certainly cannot be expected to exhibit that variety. Williams and Slater echo the experiences of dozens of others when they report that of 500 appendices removed routinely

in the course of operation for other conditions, and in no instance giving rise to demonstrable symptoms, one-third showed evidence of the changes usually reported from the laboratory as due to chronic inflammation. I think it is Deaver who says that it is rare for an adult to possess an appendix normal in every respect. If that is true and if it proves anything, it would seem to prove that abnormalities of gross appearance are not necessarily pathological. We are rapidly becoming a people without tonsils. Does Deaver's statement herald the day when we shall be a people without appendices also?

To return to the clinical picture of this second, non-recurrent type of appendicitis, improperly described as chronic, its symptoms are as vague as the disease they are supposed to arise from. They usually start with pain in the right iliac fossa, though a study of the anatomy and nerve supply of this region should be sufficient to assure us that disease in the appendix does not primarily so manifest itself. They include vague gastric symptoms and even gastric hemorrhage, a contention for which Lord Moynihan is largely responsible and which surgeons who lack his discerning judgment and his technical skill have turned to evil account. They comprehend such far-fetched manifestations as colitis, arthritis, neuritis (focal infection is still the god of many) menstrual irregularities, nervous disturbances, melancholia, inability to think clearly, and even angina pectoris. Hertzler has collected most of this sorry list and I am inclined to agree with him in his caustic comment that when he has contemplated it, he becomes afflicted with all the symptoms himself.

The diagnosis of this type of appendicular disease is an unsatisfactory affair. Literally a dozen conditions must be differentiated from it, ranging from simple constipation to intercostal neuralgia. Royster lists 14 different signs, advanced by 14 different people, all of them an-

nounced by their authors as definitely diagnostic, and most of them having to do with the location of pain or tenderness at a fixed point or as a special reflex. Hausmann may have been the first to express it, but he was not the first to realize that a fixed point on the abdominal wall can never correspond to an inconstant point within the abdominal cavity like the insertion of the appendix. It seems to me, too, that an intra-abdominal disease which must be eliminated by such remote methods as an investigation of the sinuses, the eyes and the sacroiliac joint, though I am far from denying the interrelation of all bodily parts, has a hard case to prove.

The laboratory in general, the x-ray laboratory in particular, frequently mean nothing but an added expense for the patient. Both the absent and the visualized appendix are variously supposed to indicate pathology. Carman, than whom no more practical radiologist ever lived, pointed out that every single x-ray finding, even the pressure-tender point accepted as infallible by most of his brethren, can be discounted in some way. In his opinion the exclusion of pathology in the stomach and duodenum is the most valuable service the x-ray can perform in this connection, and he adds—it is queer how everyone tends to cynicism in the discussion of chronic appendicitis—that the x-ray signs of it depend largely upon the examiner's intensity of endeavor and degree of enthusiasm.

For my own part, I would bid you beware of the acceptance of pylorospasm as a sign of anything. I can recall offhand a dozen people who today, as least as far as I am concerned, would be without their appendices had I been led into surgery by this sign and the insistence which the radiologist placed upon it. Most of these patients, by the way, had diagnosed their own disease. They had appendicitis on their minds if not within their abdomens and they furnish one of my reasons for wondering, in moments

of discontent, whether we may not be teaching the laity too much about the diseases to which humankind is liable.

Again, there is a difference of opinion as to whether this so-called chronic appendicitis predisposes one to acute appendicitis. One writer seriously suggests that possibly the reason for the increased death rate in acute appendicitis, which is most regrettably the present situation in that disease, is that we are performing fewer operations for chronic appendicitis. That may be his experience, but most of us do not live in such favored localities. Royster states that those cases of acute appendicitis in which the pathologic findings are out of all proportion to the duration of the disease are evidences of an acute exacerbation of long-continued chronic changes. Personally, I find it simpler to consider them illustrations of fulminating pathology. Many pathologists, as a matter of fact, believe that the acute exacerbations of recurrent appendicitis actually cause milder pathologic changes than does the single clinical explosion of the true acute disease, though others take the opposite view. At any rate, the point is open to argument on both sides.

I have been impressed, in a casual reading of the literature, with the fact that most of the writers on the subject of chronic appendicitis, except the iconoclastic Hertzler, seem to be on the defensive. They have a case to prove, and be it conceded that most of them make out a good one. But one thing strikes me as very curious. Granting that persons with pain in the right iliac fossa and vague digestive disturbances should be treated by appendectomy and that benefit sometimes follows; granting that chronic appendicitis does exist as a clinical entity; granting that Deaver and Moynihan are right, granting that Hertzler and Walton are wrong (for the opponents and proponents include such illustrious names as these); granting all of this and a good deal more, why, if these things are so and if

chronic appendicitis is a definite affection of the appendix, why in the world is it necessary in so many instances to seek an extra-appendicular explanation for it?

I have very little patience with the mechanical explanations of chronic appendicitis. I am perfectly willing to grant that most annoying and distressing symptoms may arise from interference with cecal peristalsis, from bands, adhesions, stasis, colitis, duodenal atony, reduplication of the peritoneum and other mechanical abnormalities. I am perfectly willing to agree with the writers who claim that in the presence of such associated conditions mere appendectomy will not give relief, and that other procedures, some medical, some surgical, are indicated also. But why then term the condition chronic appendicitis? Carnett and Boles, in a very excellent paper, advance the theory that chronic appendicitis is not a disease limited to the appendix but is a more or less generalized condition involving the colon and other portions of the gastrointestinal tract, as well as the sensory nerves of the abdominal wall, and seen most frequently in constitutionally inferior types with a predisposition to functional disease. All of which is quite true. No one is readier to admit than I that such a syndrome can give rise to a great deal of trouble. But why call the disease chronic appendicitis and then point out that the appendix really has little if anything to do with the condition?

In short, let us do a little clear thinking. Let us admit that acute appendicitis exists. Let us admit that recurrent appendicitis exists. But let us admit also that it is most unreasonable to lump together a miscellaneous group of symptoms, extra-appendicular, mechanical and constitutional, and call the medley chronic appendicitis, when the syndrome has no relation at all to disease in the appendix as we know it exists.

The test of the correctness of diagnosis and treatment in any disease is the end-result, from the viewpoint of the patient.

But it does not follow that experimental appendectomy is justified because in some cases it relieves symptoms. Other things must be considered, the period of disability, the cost to the patient in dollars and cents, and the actual risk to life. Appendectomy is not an operation entirely devoid of risk. Warnshuis collected 5664 surgical cases of chronic appendicitis from 35 hospitals, and found a mortality of 1.68 per cent. It ranged from 0 on single services in some institutions to 2 and 3 per cent in others. The mortality in nearly 10,000 cases done at Charity Hospital and Touro Infirmary in New Orleans over a six-year period was considerably less than 1 per cent. Yet in these supposedly clean, uncomplicated cases the causes of death included peritonitis, sepsis, obstruction, shock, embolus, secondary hemorrhage and organic disease. A list like that offers reasons for earnest thought. It includes some preventable surgical causes, some unavoidable accidents, both of which may come to pass in the best hands, though not so often as in less good hands. For we must remember, as I have already pointed out, that because appendicitis is supposed to be a simple disease and appendectomy a simple operation, the occasional surgeon gets in his deadliest work in this field. That is more than an impression; it has been proved statistically.

Granting, however, that the patient emerges with his life, as he does in the vast majority of cases, what happens then? Well, according to published figures, he has a 15 to 50 per cent chance of receiving no benefit at all. Many patients are considerably worse, especially the neurotic patient, with whom a simple appendectomy is often the starting point for as many abdominal operations as she (it is usually a she) has organs to be removed, after which there can always be laparotomies for adhesions. But the thing that interests me in the series reported by Deaver and Ravdin, by Holder and Menninger, by Gibson and many others, is that the great majority of all the patients gave a history

of previous acute attacks. That is the catch in every such series, or rather, to put it more correctly, that is the rational explanation of successful surgery. This is appendicitis of the recurrent type, for which surgery is indicated and in which surgery is justified, and it has nothing to do with the vague disease we are endeavoring to put in its place.

I am far from denying that abdominal and constitutional symptoms frequently urgently demand operation; but my point is that we should do away with the diagnosis of chronic appendicitis, which means nothing, and frankly set ourselves down for exploratory laparotomy, which may mean anything. Then, having been lucid mentally, let us make our actions correspondingly logical and let us do our exploration through a proper incision. The McBurney incision in chronic appendicitis is the curse of surgery. My own opinion is that it is indicated only in 1 group of patients, boys under sixteen, in whom it might be preferable to do a secondary operation rather than to weaken the abdominal muscles. I shall not enter upon the vexed and highly speculative question of whether the appendix is a predisposing factor in lesions of the upper abdomen; I am simply pointing out that appendiceal disease of the non-recurrent type is often associated with lesions of the gall-bladder and of the gastric area. A third of the patients who consult me for these latter conditions, in both of which, as in appendicitis, pylorospasm is a marked feature, give a history of previous appendectomy, in 9 out of 10 cases through a McBurney incision. Within the month I have operated on a young woman for duodenal ulcer and gallstones who, less than a year ago, had her appendix removed through a McBurney incision for precisely the same symptoms which I hope my recent performance is going to rectify. I have seen chronic appendicitis handled through a McBurney incision develop into ureteral calculus, ureteral stricture, floating kidney, ectopic gall-

bladder, cecal diverticula, tubal and ovarian pathology, and biliary and gastric lesions. Even more tragically, I have operated on patients with hopeless malignancy of the upper abdomen who had had a so-called chronic appendix removed through a McBurney incision.

I grant all that can be said in its favor, the speed with which the operation can be concluded, the absence of shock from exposure of the internal viscera, the swiftness of recovery, the inconspicuousness of the scar. But under the conditions of civilized life and customs I have never felt that the last argument was a very valid one, and against the first arguments I would advance two others. One is that the appendix does not always lie ready to hand, in which case there is nothing swift or smooth about one's performance. I have recently removed an appendix which lay under the liver and was adherent to the duodenum, and my task was none too easy through a right rectus incision of generous proportions. The second is that the McBurney incision does not permit the complete inventory which should be a part of any abdominal operation in which special contraindications do not exist, and which should never be omitted in any instance in which laparotomy is done for supposed chronic appendicitis.

Mr. Walton of the London Hospital has had as wide an experience in abdominal surgery as any man living. He has recently reported 982 cases of appendicitis, 722 of them acute, and in the remaining 360 all but 11 patients having had at least 1 acute attack. He has done 1738 operations for upper abdominal lesions, and although it is his custom routinely to remove the appendix if it is grossly pathologic, he found appendectomy necessary in just 4 per cent of these cases. His follow-up is excellent; I have personally seen it in

operation and I can testify to its effectiveness. Yet in spite of the part the appendix is supposed to play in gastrojejunal ulceration, less than 2 per cent of the patients operated on for peptic ulcer returned with this complication, and only .28 per cent of the whole group later developed acute appendicitis; their risk was far less, I am sure, than it would have been with the routine performance of appendectomy.

In the face of figures such as these, published from such an authoritative source, I believe the case for chronic appendicitis of the non-recurrent type cannot stand. For my own part, I accept them unreservedly and I hereby announce that I have joined the ranks of the cynics. I may not quite agree with the wit who put appendicitis into 2 classes, the acute variety and the variety for revenue only. But I am wholly one with the eminent medical gentleman who, when questioned concerning the function of the appendix, replied in all seriousness that it contributed largely to the support of a noble profession.

WHY A HOSPITAL DEPARTMENT OF RADIOLOGY AND WHENCE THE RADIOLOGIST?

THE radiological department of a hospital should not only furnish appropriate assistance in the routine examination and therapeutic management of patients, but should make important contributions to the staff conferences, assist in the instruction of internes and the other members of the staff concerning the application of radiology to the problems of diagnostics and therapy, including the possibilities as well as the limitations of the roentgen ray aid, and help in various research problems as they present themselves. Incidentally it should be remarked that the hospital management should not look upon the radiological department as a profitable investment, and it should not be considered a duty of the department to contribute to the financial upkeep of the institution until all the foregoing objects have been achieved. There is no more justification for the hospital to capitalize the experience and services of the physician specializing in radiology, than to put the operating room on a fixed-fee basis, pay the surgeons and nurses salaries, and credit the profits to the income of the hospital.

In order to meet the foregoing aims the department personnel must include a physician-radiologist. It is difficult to understand the attitude of some hospitals where the staff is apparently willing to delegate the management of the radiological examinations and their interpretations to laymen doing radiology. The writer recently saw a formal written report of several examinations, including a Graham test and a gastrointestinal study after the opaque meal and an enema, ending with an opinion as to the existence of several pathological conditions, signed by a layman doing radiology. The patient had been referred to this layman by a physician!

In order to attract men of broad capabilities to the field of medical radiology

the medical profession as a whole should recognize its duty in regard to lay radiologists and stop to consider what should be its attitude toward the hospital radiological department. For the good of the service this department must not become a photographic center for the production of pictures to be interpreted by the various surgeons, internists or specialists who may have ordered the x-ray studies. There is a growing tendency to look upon the x-ray department as just this type of photographic laboratory, the roentgenograms being sent to the ward or office where the original referring physician often appears willing to make his own readings and seems perfectly content to assume full responsibility for the radiological diagnosis. We should look ahead to see where such a practice leads.

Does it mean that the chest films are to be sent to the department of pulmonary diseases, the gastrointestinal films to the gastroenterological department, the head films to the neurological department, etc.? If so, what about the fluoroscopic examinations? What future can be seen for the radiological department other than as a photographic laboratory, and what need for an experienced physician-radiologist in such a place? Such a development would mean setting back many years the clock of radiological progress, for it would mean the abandonment of all help obtainable from screen studies by a medical radiologist with his accumulated experience of many years in examining patients from all departments of a hospital, to say nothing of his private practice.

We do not wish to intimate that an internist or other specialist has not a perfect right to fit himself in every possible way for the practice of his specialty; and if he wishes to utilize the roentgen rays as one of the methods of study, there can be no logical objection raised to his use of this procedure. It is his need to see that

he has had sufficient training under expert tutelage for the radiological work. But if the hospital should be so unwise as to divide up its radiological work, apportioning it out to various departments, there would be lost that great help to physicians, surgeons and radiologists which comes from frank discussion of the roentgen findings between radiological specialist and referring physician, and their proper evaluation in the light of the clinical aspects of the case which such discussion naturally and inevitably brings out.

The roentgen report should contain only statements which can be substantiated from radiological evidence. This report will then take its place with the other evidence of the case, from which the clinician in charge will draw his conclu-

sions; but if the staff members have the slightest interest in the development of a capable radiologist whose usefulness will continue to enlarge, they will leave no stone unturned to keep him posted in regard to his cases, tell him of his successes as well as his failures and send for him when the surgeon or pathologist has let the light of day upon a lesion which has been baffling. Thus not only will he be likely to become a more skillful radiologist but he will surely broaden out into a better and more useful consultant. With such an interesting future in prospect for the radiologist, there will be no difficulty in attracting from the ranks of experienced clinicians capable physicians willing to devote themselves to the specialty of clinical radiology. JAMES T. CASE.

REPORT OF THE RECENT JOINT MEETING OF THE BRITISH & AMERICAN ORTHOPEDIC ASSOCIATIONS*

THE credit for the trip of the American Orthopedic Association to Europe belongs entirely to Dr. Albee. One of his first suggestions as president-elect was that we should go to England for a joint meeting with our British colleagues. The officials of the British Orthopedic Association were favorably disposed toward the proposal of a joint convention. The idea took root and the meeting was officially authorized a year ago in Washington.

The preparations for the meeting were then undertaken under the supervision of the Executive Committee of the American Orthopedic Association. Dr. Ellis Jones, of Los Angeles, the Chairman of the Program Committee, requested me to arrange a clinical program to be presented in New York. This is ordinarily given in one day. However, because of the long journey ahead of us, and because many of the members who could not go

abroad would gladly attend a meeting in New York, I decided to extend the clinical session to two days. It seemed desirable to cover a large variety of subjects and to let the work of each man represent that in which he excelled. Consequently I arranged a series of operative clinics for the first day. Each surgeon prepared to perform those operations in which he was specially interested. In addition there were sarcoma and arthritis clinics. On the second day all the presentations were, as a matter of convenience to the visitors, made at the Hospital for Ruptured and Crippled. These included, besides strictly orthopedic cases, related bacteriological, pediatric and neurosurgical subjects. The clinical meeting was attended by more than 200 surgeons. The visiting surgeons commented very favorably upon the program, and expressed the opinion that they had profited by their attendance.

Up to five years ago the annual orthope-

* Read before The Section of Orthopedic Surgery, New York Academy of Medicine, Oct. 18, 1929.

dic meetings began at 9 A.M. the first day and terminated abruptly at 5 P.M. the last day. As there was no relaxation from the cold, strictly scientific program during the entire convention, attendance sometimes became an ordeal. About five years ago, when the meeting was to take place in Baltimore, Dr. George Bennett arranged that the convention be held on board a steamer sailing down Chesapeake Bay, and the members' wives were invited to accompany them. This introduced a custom which has contributed greatly toward the pleasure of the annual meetings, and has converted what used to be a mere scientific obligation into a much-sought-for vacation. Accordingly, as there were many ladies going abroad with us this year, appropriate entertainment was provided for them in this city on the day before sailing. The necessary funds were generously donated by the orthopedic surgeons of our city. The details were looked after by Mrs. Armitage Whitman, Mrs. Kleinberg and several others. The visiting ladies were taken to various interesting parts of our city. In the evening we were all the guests of Dr. and Mrs. Albee at a very delightful banquet in the Commodore Hotel.

Our voyage across the Atlantic was nothing short of delightful.

After a restful voyage of nine days we arrived in Glasgow.

After crossing Loch Lomond, we were taken by old fashioned stage-coaches to Loch Katrine. Our coachman was of the traditional type described so well by Washington Irving in the Sketch Book. He wore a bright red coat and a broad rimmed low derby set at a slight angle. He was stout and had a ruddy plethoric complexion. His mien was very serious and he held his station on the box with becoming gravity and dignity. Each coach had what looked like a frail body mounted on thin wheels.

On the following day we were taken by special train from Edinburgh to Liverpool, Liverpool which to us means Sir Robert Jones, that charming, genial, wonderful

man. He was our host at dinner that night. Months previously he had requested me to extend an invitation to everybody in our party, men and women, members of the American Orthopedic Association and all other visiting surgeons, to be his guests. His hospitality and warm welcome will forever remain with us as a beautiful memory. To be interested in orthopedic surgery is a passport to Sir Robert's friendship. We were with him almost continuously for four days. His depth of information, his skillful hands, his wise and liberal counsel, his tireless energy and his ever kindly and warm smile, alike for everybody, form memories that will serve to make of us better orthopedic surgeons and better men.

On the next day, July the third, there was a scientific program which lasted from 9.30 in the morning until 6 o'clock in the afternoon. The meeting in the morning was held in the "Medical Institution" of Liverpool, which is, I take it, the equivalent of our Academy of Medicine. Sir Robert Jones read a paper on "Fractures and Bone Setting" giving us many points of very great value in connection with the treatment of fractures and injuries in the vicinity of the joints of the upper and lower limbs. He stressed the importance of the position of abduction in the therapy of shoulder disabilities. He described lucidly and demonstrated his method of reducing dislocated semilunar cartilages. He practically makes the patient reduce the dislocation. The procedure is as follows: The limb is flexed and as the surgeon rotates the leg inward, the patient is instructed to kick violently. In this act the cartilage usually slips back into place. Sir Robert also showed us the most practical manner of reducing a Colles' fracture, and indicated that the best attitude for subsequent immobilization is that of palmar flexion and ulnar deviation of the hand. He also demonstrated the use of malleable iron splints. He spent considerable time on the subject of parietal adhesions. According to Sir Robert a joint that has periarth-

ritic adhesions should in a so-called stretching be moved once to the fullest extent in all directions and then left alone. Repeated, forced and painful movements irritate and should be avoided.

Mr. MacFarland, one of Sir Robert's junior assistants read a paper on "Fracture of Lower Tibial Epiphysis," and Mr. Watson Jones, discussed the "Primary nerve Lesions in Injuries of Wrist and Elbow." Both papers presented excellent reviews of these subjects and were beautifully illustrated with original drawings and lantern slides. Mr. MacFarland laid great emphasis on the need of so reducing the fragments in a fracture that the articular surfaces will have normal alignment. This will assure the best functional result.

In the early part of the afternoon there was a surgical clinic, and both Sir Robert and his Senior Associate, Mr. MacMurray operated. Sir Robert did an osteotomy of the tibia and fibula for old malunited Pott's fracture, obtaining a complete correction. Mr. MacMurray removed a loose internal semilunar cartilage through a vertical incision that was no more than $1\frac{1}{2}$ in. long. The operation was performed very rapidly and most dexterously. Hardly before we realized it the cartilage had been delivered and removed. The technique was carried out with ease, grace, the minimum of trauma and the maximum of efficiency. Using a small incision it was necessarily impossible to extirpate the whole of the posterior horn of the cartilage, and I gathered that Mr. MacMurray believed that it did no harm to leave a small tab of cartilage. This has interested me particularly because in my last few operations I have used rather liberal incisions to permit removal of the entire cartilage. However, Mr. MacMurray's method is probably the better procedure.

At 4 o'clock, according to the time-honored and delightful English custom, all work was stopped and tea was served. We should adopt this custom in our country, as a means of increasing our

efficiency. The interruption of half an hour is just long enough to permit general relaxation and is very refreshing. During tea, Sir Robert was naturally the center of attraction and he radiated good cheer. He delighted particularly in relating how he overcame some of the obstacles he encountered when he was compelled to operate in the country with inexperienced assistants. One of these stories especially lingers in my memory. In travelling to perform an operation in the country he always took along a tight and rigid pair of operating gloves which were very difficult to put on. He and his nurse had an arrangement that when either observed the assisting physician to be careless or not conversant with proper surgical technique, he or she would suddenly announce the need of changing gloves. The nurse would give Sir Robert his gloves and the special pair to the assistant. While the assistant was laboriously pulling on his impossible gloves, Sir Robert, who is an unusually fast surgeon, completed the operation. All was well and the assistant none the wiser.

After tea there was a dry clinic in which Mr. MacMurray demonstrated a large number of cases of congenital dislocation of the hip treated by manipulation and by open operation. Their system of treatment of these cases is much like our own. They reduce the dislocation by manipulation whenever possible and reserve the open method for the resistant and more difficult cases. The results of the manipulation were unusually satisfactory as many of the patients had a practically normal range of mobility. Mr. MacMurray then showed a rather large series of cases of paralytic calcaneocavus in which Sir Robert Jones' operation of section of the os calcis and backward displacement of the posterior fragment was performed. These, from my point of view, did not have good results. There still remained a prominent heel, a heel gait, and an unstable ankle because the foot went into abnormal dorsal flexion during walking. There was a lack

of the firmness and stability of the ankle, and of the resistance of the foot against the leg that characterize the effectiveness of the Whitman astragalectomy with backward displacement of the foot. Mr. MacMurray then exhibited particularly favorable results from arthrodesis of the hip for osteoarthritis. At my request he described Sir Robert's method of mobilizing the hips in cases of very advanced osteoarthritis. This procedure is particularly valuable when both hips are involved. The steps of the operation are as follows: The great trochanter is cut off with the pelvitrochanteric muscles attached to it. The femur is cut across at the base of the neck and a liberal segment of bone is removed. The trochanter is then turned down and secured to the base of the neck. The shaft of the femur, now entirely detached from the neck, has free play. The result is a fair range of motion at the hip. I saw a very good result of this operation demonstrated in Dr. Allison's clinic, and was surprised that, although the femur is cut across, the limb is quite stable. Mr. MacFarland showed 2 cases of congenital dislocation of the knee reduced during infancy by manipulation. Both had excellent results. A vast number of cases was presented during this dry clinic. We all wished we had more time to study them and listen to the instructive remarks of Mr. MacMurray. The clinic was stopped at 6 o'clock, although there were many patients waiting to be exhibited, because we had to catch a train to go to London.

I learned a particularly interesting fact from Mr. MacMurray in regard to the economic value of the panel system in England. As you know in England the poor families are assigned to groups or panels, each of which is attended by a general practitioner at a stipulated amount per year. The assignment to a special panel is by mutual consent of the patient and the doctor. Each has the right of choice and refusal. The remuneration is small but fair and gives the panel physician

a satisfactory annuity. Mr. MacMurray assured me that the panel doctors had a good income and were pleased. This is entirely different from the state of affairs in Germany where the doctors receive such small remuneration that their work is virtually free, but with the disadvantage to the physician that he is compelled to treat a large number of patients both in their homes and in his office at all hours of the day and night. Then, too, in England, a patient belonging to a panel cannot, or rather through custom does not, visit a consultant without a letter of introduction from his attending physician. This materially diminishes the tendency to visit many clinics and many physicians in the same specialty.

The joint meeting of the British and American Orthopedic Associations was called to order at the Royal Society of Medicine at 9.30 A.M. on Thursday, July 4 by the celebrated Mr. Hey Groves, president of the British organization. There were present on the officers' platform in addition to Mr. Hey Groves, Sir Robert Jones, Dr. Fred Albee, Mr. A. S. Blundell Bankart, secretary of the British Orthopedic Association and Dr. De Forest P. Willard, secretary of the American Orthopedic Association. There was an audience of between 150 and 200 surgeons, among whom were the versatile Murk Jansen, the charming Jacques Calvé, and the handsome Vittorio Putti. Among the British surgeons present there were many who are well known to us through their work and writings, namely, Mr. Fairbank, Mr. Elmslie, Mr. Ollershaw, Mr. Platt, Mr. Bristow, Mr. Naughton Dunn and Mr. Laming Evans, all of whom have been identified with orthopedic surgery for many years. After a brief but very cordial welcome by Mr. Hey Groves on behalf of our British colleagues, the scientific session was begun.

The subject for discussion for the first day was fracture of the neck of the femur. Mr. Hey Groves read an interesting paper reviewing the different methods of treat-

ment and their results. His figures covered a rather small number of cases and showed what might be called only moderately satisfactory results. He used the abduction method and also the open operation with about equal frequency. He was, however, decidedly in favor of the conservative treatment. In the cases requiring an open operation he preferred a beef-bone graft to an autogenous peg. In general, he was not enthusiastic about the results in fractures of the hip, and emphasized the disadvantages that arise from the necessarily prolonged immobilization.

Mr. Groves was followed by Dr. Royal Whitman. Dr. Whitman received, as he mounted the platform, a very warm reception and loud and prolonged applause. Dr. Whitman briefly reviewed the mechanics involved in fracture of the neck of the femur, the purpose of treatment and the elements in the abduction treatment which aimed to meet the needs of the injury. In clear and convincing style, in few but beautifully chosen phrases he proved that the only logical treatment for a recent fracture of the neck of the femur was the abduction treatment. He expounded the theory and described the details of his reconstruction operation for old cases of fracture of the neck of the femur. He exhibited many lantern slides that proved beyond any doubt the truth and force of his statements. He presented such strong arguments in favor of the method he advocated, that the principles of his system of treatment were driven home to all of us permanently. When Dr. Whitman sat down there was, I am sure, no doubt in the mind of any surgeon present that the abduction treatment was the most effective procedure and the method of choice for the early cases of fracture of the hip, not only as a means of treating the injury, but as the best method of safeguarding the general health and the future welfare of the patient. This conviction was voiced by many in the discussion which followed.

Dr. Phil Wilson read a short paper on

the use of a special metal pin for fractured hips devised by Dr. Smith-Peterson. He exhibited the pin, with which we in New York are already acquainted, and related the results in the cases operated. Our British colleagues were impressed with its value and were much interested in the technic described by Dr. Wilson. Dr. Albee in his discussion was in favor of the use of an autogenous bone peg. He seemed surprised that it had not already been universally adopted. He exhibited Dr. Sterling Bunnell who had sustained a fracture of the neck of the femur and who obtained an excellent result from a bone peg operation done by Dr. Albee. Dr. Bunnell very kindly performed for us jumping upon a chair and going up and down the short flight of stairs leading to the platform, two steps at a time. Mr. Bristow showed 3 cases of fracture of the hip which had excellent functional results. He and Mr. Ollerenshaw definitely favored the use of the abduction method for all early cases. Dr. Whitman in closing the discussion presented Dr. Morrison of Brooklyn, who had accompanied us to Europe. Several years ago Dr. Morrison fractured his left hip but did not consult Dr. Whitman until one month after the injury. The abduction treatment gave him a firm union and a most satisfactory functional result. The doctor walked very well, without a cane or discomfort and without any concern about his hip. The morning's discussion of fractured hips left no doubt that, while bone pegging and the use of steel pins and other operative procedures may give good results in the hands of a few, the Whitman abduction treatment was the most direct and the most effective procedure for early cases at all ages. Its application was specially valuable for old people as it permitted the necessary hygienic care and change of posture imperative during a treatment which is inevitably long.

Dr. Putti read a paper on the diagnosis and treatment of congenital dislocation of the hip during early infancy. He aimed

to discover the dislocation before the child began to walk. With that in view, he has been training the public to bring their infants for routine examinations of the hip. His efforts are facilitated by the acquaintance of the people with this lesion on account of the vast number of cases of congenitally dislocated hips in Italy. He has found that the x-ray pictures of even very young infants who are going to have dislocated hips will show a diminution in the size of the centre of ossification of the femoral head, an upward displacement of the femur and a flattening of the acetabulum which are pathognomonic. Children whose hips show these defects are treated immediately by gradual abduction of the legs on a specially constructed triangular mattress or a double leg brace. The limbs are gradually abducted to the fullest and maintained in that attitude until the possibility or danger of a dislocation of either hip is passed. Dr. Putti feels that he has saved those children whom he has so treated from having dislocations. His series is still small. The paper was received with great enthusiasm as the new idea presented appealed to all of us as possessing considerable merit.

In the evening of July 4, the officers of the American Orthopedic Association were guests at a dinner given by Mr. and Mrs. Hey Groves. The cordial attitude of our British colleagues toward us was portrayed by Hey Groves on the cover of the menu. At the top were the British and American flags. Immediately below were two gloved hands representing the surgeons of both orthopedic associations in a firm and friendly clasp. Below the hands was the inscription July 4th, 1929, indicating that we were very welcome to the British on our Independence Day. In the middle of the page was a drawing of a fractured tibia and fibula. One tibial fragment represented Great Britain and the other the United States of America. The fragments were joined by an inlay graft of Friendship. Below this drawing was the

significant inscription "Natural Union without Artificial Ties or Foreign Bodies." The bottom of the page was decorated with drawings of an Albee electrically driven motor saw, a fracture of the neck of the femur cured by the abduction method and a Thomas brace.

After dinner we attended a reception at the Royal College of Surgeons of England. We were received by the President, Lord Moynihan, and Lady Moynihan and Mr. and Mrs. Hey Groves. Sir Arthur Keith delivered a lecture on the evidences of bone and joint disease in prehistoric times, showing specimens of bones with syphilitic lesions, myositis ossificans and skulls with numerous fractures and trephine holes. The Museum contained a vast collection of beautifully mounted pathological organs which stirred one to the desire to spend one's whole vacation studying them. In the Great Halls were portraits of some of the old masters in medicine by Sir Joshua Reynolds, Lawrence, Romney, Hogarth and others. The portraits are all interesting and in good state of preservation except that of John Hunter which is unfortunately blurred and rapidly fading. While we wandered through the building we listened to the strains of delightful music by the Marguerite Wortham Orchestra. The evening was terminated by the serving of delicious refreshments in the Library of the College.

The subject for Friday, July 5, was reconstruction surgery in paralytic deformities of the lower legs. In Dr. Henderson's absence Dr. Bruce Gill read his paper. Dr. Henderson reviewed the various procedures for stabilization of the knee and ankle joints with which we are all fairly familiar. He emphasized the advantage of combining tendon transplantations with bone operations. Mr. Laming Evans then read a paper in which he detailed the pathology of the various paralytic deformities and their treatment. He was very pessimistic about all tendon operations, stating that he had never seen a good result even from a

biceps transplantation for quadriceps palsy. The papers were followed by considerable discussion. Dr. Frank Ober confirmed Dr. Henderson's statement that the best results are obtained by a judicious combination of tendon transplantations with bone surgery. He exhibited lantern slides showing good results from the transplantation of the tibialis posticus for paralytic varus. Mr. Naughton Dunn emphasized the value of panarthrodesis. Dr. Leo Mayer described his method of physiological tendon transplantation, and demonstrated the technic in a series of very cleverly arranged muscle charts which he uses for his students. His method and exhibition were enthusiastically applauded. Dr. Whitman in his discussion pointed out very patiently the advantages of the astragelectomy with backward displacement of the foot in the stabilization of the ankle. At the end of the session I felt sure of three things: First, a strong biceps femoris muscle transplanted to the front of the knee for quadriceps palsy will give a good result. Secondly, an active tibialis anticus tendon transplanted to the outer side of the foot will maintain the correction of a varus and give a good functional result. Thirdly, an astragalectomy with backward displacement of the foot will stabilize the ankle in cases of paralytic calcaneus and dangle foot. Good results from these operations are practically assured if the surgeon uses proper technic. For all other conditions and in the use of any of the other methods, the results are uncertain and often only of short duration.

In the afternoon there were several operative clinics. About fifty of us went to Mr. Bristow's clinic in St. Thomas's Hospital. I saw Mr. Bristow remove an internal semilunar cartilage. He used a very short, almost transverse incision. He exposed the central part of the cartilage and lifted it up on a hook; he then rapidly freed and cut the extremities of the cartilage. The operation took only a few minutes and was performed with the skill of an artist. Mr. Perkins applied a Delbet

walking splint for fracture of the lower third of the leg and stated that he had had very good results with its use. Although the St. Thomas' Hospital is a very old one, having been opened by Lord Lister, the operating room equipment is modern and complete.

After the operations there was a demonstration of patients by Mr. Bristow, Mr. Perkins, Mr. Page and Mr. Brockman who won the Sir Robert Jones medal this year for research work in orthopedic surgery. There were exhibited a very large number of exceedingly interesting cases of osteochondritis dissecans, epiphyseal injuries, sunken acetabula, fixations of scapula for serratus magnus palsy, arthrodesis of the hip, coxa vara, arthrodesis of the ankle for malunited Pott's fracture, osteotomy for osteitis deformans, renal rickets and reconstruction of the hip. Mr. Page showed 2 cases of fixation of the scapula to a dorsal vertebral spinous process for paralytic wing scapula. The cosmetic and functional result was excellent. Several cases of Paget's disease were shown in which an osteotomy had been performed to correct lateral or anteroposterior deformity. The result was eminently satisfactory; the fracture united perfectly and the deformity remained corrected. The sectioned long bones of a case of advanced renal rickets in an infant were exhibited by Mr. Brockman. The bones showed marked changes at the epiphyses and explained the fuzzy appearance usually seen in the x-ray pictures of a rachitic lesion. The cases of malunited Pott's fracture for which an arthrodesis of the ankle was performed had particularly good results. The patients walked well and with a surprisingly elastic gait. The clinic terminated with a rather lengthy demonstration by Dr. Mennell of cork foot supports. He showed us how he prepares various cork splints for flat feet, anterior metatarsalgia and shortened limbs. His technic was clever, but the splints were rather bulky and clumsy, and not nearly so nice nor so effective as the simpler foot braces we make in our city.

The Dinner of the Associations was held on the evening of Friday, July 5, at the Cafe Royal. Sir Robert Jones was the chairman. Addresses were delivered by the chairman, Prof. Hey Groves, Dr. Albee, Dr. Joel Goldthwaite, Sir Squire Sprigg and by His Majesty the King of Portugal, who for many years has been interested in the rehabilitation of the disabled. The dinner was a huge success. The acquaintance of the American and British surgeons had already ripened into warm friendship, and both at the head table and throughout the room, there were frequent expressions of great satisfaction with the joint meeting.

On Saturday, July 6, six short papers were read by members of the American Orthopedic Association in the morning, and in the afternoon we visited the Lord Mayor Treloar Cripples' Hospital and College at Alton, of which Sir Henry Gouvain is the medical director. The Treloar Hospital and College is an institution for tuberculous children. It is located amidst beautiful country and occupies about 60 acres of ground. As the name implies it affords hospital care for the sick, and has a college for the training of these children who have recovered sufficient to be able to do some useful work. The hospital occupies many buildings and cares for a large number of children with tuberculosis of bones, joints, glands and the skin. The patients get excellent hygienic care and splendid orthopedic treatment. Heliotherapy is employed very extensively. There is one whole building filled with a large variety of electrical apparatus for the administration of heliotherapy. One is almost impressed that too much confidence is placed in this form of treatment. I never saw such extensive tuberculous skin lesions as we saw there. There were many cases with their ears and noses destroyed by the tuberculous disease, and no end of cases with severe facial disfigurement. All these lesions were healing, and the patients appeared in excellent general condition.

The institution is under the supervision of the Department of Education and hence there is ample provision for the instruction of all the children. The girls are taught weaving, basketry, knitting and sewing in all its branches. The College is located in a separate building at some distance from the hospital. In it boys between fourteen and eighteen years of age are taught the manufacture of shoes, clothes and leather goods. The atmosphere and the surroundings of the Treloar Cripples' Hospital and College are exceedingly cheerful and are not only conducive to an improvement in health, but also to the acquirement of a liberal education, a remunerative trade, and to the development of a sense of usefulness in the community.

We returned to London about 6 o'clock and bid our British colleagues farewell. They expressed the hope, and we the sincere wish, that they would meet with us in America in the very near future. The joint meeting of the British and Orthopedic surgeons established between us, living in widely separated countries, a feeling of nearness and intimacy, a sympathy and understanding that will inevitably lead to a more thorough appreciation of each other's work, and to the early adoption of the best methods of treatment for our patients. Thus ended a very delightful and instructive convention that I trust will be the forerunner of many more.

SAMUEL KLEINBERG.

SOCIETY NOTICES

BEGINNING this year the American Association for the Study of Goiter will award a cash prize of \$300 annually for the best original thesis dealing with some phase of the goiter problem. Theses should be submitted by June 1, to Doctor Walter M. Simpson, Chairman of the Essay Committee, Miami Valley Hospital, Dayton, Ohio. The award will be given immediately following the coming meeting of the Association which is to be held in Seattle, Washington, July 10-12, 1930.

"PURKINJE'S CELLS"

JOHANNES EVANGELISTA PURKINJE was born in 1787 in Bohemia. He was a scientist interested in many different fields of work but he is known to posterity as a pioneer in the employment of the microscope and also as a genius in the field of physiology.

Purkinje was the first to use the microtome, Canada balsam, glacial acetic acid, potassium bichromate, and the Drummond limelight in his microscopical labors.

In 1825 he described ("Symbolae ad ovi avium historiam ante incubationem") the germinal vesicle in the embryo. He was the first histologist to use the word or term "protoplasm." In 1833, in a student's dissertation, there was described his discovery of the sudoriferous glands of the skin with their excretory ducts. His other important discoveries include the pear-shaped ganglionic cells in the cerebellum (Purkinje cells), the lumen of the axis-cylinder of nerves and the ganglionic bodies of the brain. With Gabriel Valentin collaborating, he published his renowned article on ciliary epithelial motion. He described the fibers of the cardiac muscles (1839) and of the uterus (1840). He antedated Schwann by two years in his work on artificial digestion. It is interesting to read that he pointed out (1823) the value and importance of finger-prints, giving detailed and accurate descriptions of the figurations. This work was done long before that of Francis Dalton.

Purkinje noted that deaf-mutes can hear through their skull bones. He did solid work in his descriptions of most of the subjective visual figures.

In addition to his many-sided activities, he was a pharmacologist of renown. He used himself as a subject for experiments on the action of camphor, belladonna, stramonium and turpentine.

Clinically, Purkinje was the first to study the vertigo and rolling of the eyes produced by rotating the erect body in a vertical axis. He did not comprehend the scientific significance of much of this work, but it is considered to have been the starting-point of modern laws, principles and discoveries of vestibular and cerebellar nystagmus.

Purkinje early in life was a teacher. Before this he had taken orders. He was graduated in medicine at Prague in 1819. His inaugural dissertation was on subjective visual phenomena. It is related this earned him the friendship of Goethe. It has been said that this friendship got him the appointment of professor of physiology and pathology at the University of Breslau in 1823. He continued at this post until 1850 when he left to accept the chair of physiology at Prague. During his Breslau days he founded the method of laboratory training in connection with German University teaching. In 1824, he equipped a laboratory in his home. The work done by him and his pupils was of such worth that the Prussian government (1842) erected a Physiological Institute for him at Breslau.

Purkinje's brilliant work in so many fields brings him down the years and makes him loom large among the immortal figures of science of other centuries. He lived to a ripe old age and departed this life in his eighty-third year.

STUDIES IN PALEOPATHOLOGY, XXIII

AN UNUSUAL SKULL FROM PRE-COLUMBIAN PERU

ROY L. MOODIE, PH.D.

SANTA MONICA, CALIF.

I HAVE considered in a previous paper¹ on "Surgery in pre-Columbian Peru," the association of skull injuries with trephined openings in an attempt to determine the exact relations of primitive surgery to depressed fractures. I have given there a number of illustrations showing an undoubted relationship; supporting the contention that prehistoric trephining was a deliberate attempt on the part of the primitive surgeon to relieve pain by elevating or removing the depressed cranial area, due to sling-shot wounds, club or mace injuries or by blows with other weapons.

After that paper had been sent to press I learned of a skull in the American Museum of Natural History, a pre-Columbian male skull in the Bandelier collections, which showed a most remarkable association of features which I consider sufficiently interesting to be separately described. I am under obligations to Dr. H. L. Shapiro, of the department of Anthropology, for a photograph of the right side of this Peruvian skull, given herewith.

There are three important features combined in this skull. First: the skull is

deformed artificially in the Aymara type, brought about by bandaging the plastic cranium of the young with a spirally wound cloth. Skulls of this type are seldom injured, and almost never trephined. The exceptions are given in my forthcoming paper. This skull (No. $\frac{99}{3161}$ Amer. Mus.

Nat. His.), however, shows *both* trephining and injury, as may be seen in the photograph. I have never seen another example in which Aymara deformation, injury (depressed fracture) and trephining were so definitely associated, and I have examined several hundred ancient Peruvian skulls and have studied illustrations of many more.

The depressed fracture, itself, is interesting and unusual. A large, triangular area had been crushed in by a blow from a club. No radiating fracture-lines, nor comminuted fragments are evident. The lesion is partially healed. The edges are smoothly rounded and new bone in places has bridged the fracture line. No depressed fracture has been seen like this. It has no counterpart in the more than 160 crania in the San Diego Museum examined for skull lesions.

Near the middle line there is an oval trephined opening made by a cutting

¹Moodie, R. L. Studies in paleopathology, xxiii. Surgery in pre-Columbian Peru. *Ann. Med. Hist.*, n. s. 1: 698, 1929.

instrument, possibly a copper knife or an obsidian flake. It appears to have healed somewhat, but we surmise that the tre-

phining was done *after* the injury, and probably to relieve pressure symptoms. The people who modified the skull into the Aymara deformation were for some reason, apparently, relieved of the occupation of fighting, since injured crania of this type are rare. They may have belonged to the priesthood who were devoted to the worship of the Sun. They may also have been members of the ruling

phining was done *after* the injury, and probably to relieve pressure symptoms.

The people who modified the skull into the Aymara deformation were for some reason, apparently, relieved of the occupation of fighting, since injured crania of this type are rare. They may have belonged to the priesthood who were devoted to the worship of the Sun. They may also have been members of the ruling

is not an extreme instance of Aymara deformation, but is sufficiently well marked in the far-backwardly extending vault, to justify the classification.

Trephining was undoubtedly stimulated by war injuries, and since from the nature of the weapons most of the injuries were cranial, this phase of primitive surgery may have developed as a military measure.

STUDIES IN PALEOPATHOLOGY, XXIV

PREHISTORIC SURGERY IN NEW MEXICO

ROY L. MOODIE, PH.D.

SANTA MONICA, CALIF.

SOME time ago when Shapiro's paper¹ announcing the discovery of prehistoric trephined crania in the Southwest (New Mexico) appeared, I considered the incident as too important to medical history to let the matter rest. Accordingly I wrote Dr. Shapiro asking for enlarged photographs of the trephined areas. This was rendered the more important since the original illustrations were published on such a small scale as to render all details obscure, even under a magnifying glass. It was evident that the skulls had been trephined, and that was all. The accompanying illustrations are the results of that request.

My readers may recall that prehistoric trephining has never been known in America north of Mexico. It is true that cases suggesting trephining have been described, but doubt remained, until Shapiro announced the discoveries of the American Museum. Many years ago Hrdlička discovered trephined crania in northern Mexico. Nothing is known of this primitive surgical practice in the Maya area, nor do we know that it was practiced by the Aztecs. In pre-Columbian Peru the practice was highly developed and the details are given in a forthcoming paper. The practice was not known to the pre-Columbian peoples of Patagonia. It is extremely important to follow up this subject and all evidences should be carefully studied.

An examination of the illustrations will establish the authenticity of the two cases as of undoubted trephining. Tool marks around the edges of the openings, the nature of the apertures themselves substantiate the opinion of trephining. Recently I have seen an early Indian skull found at Beverly Hills, California, with two parietal openings simulating trephined openings, but the absence of tool marks and the possibility

of the openings being persistent parietal fontanelles render the evidence uncertain. The location of the two skulls in carefully-studied, stratified, refuse of a prehistoric pueblo in New Mexico, and the high reputation of the men making the discoveries has sufficed to establish the antiquity as prehistoric. Just how ancient these remains are cannot be told, but archeological evidences elsewhere in New Mexico reveals an antiquity of more than two thousand years for some of the inhabitants of the Southwest.

The cranium shown in Figure 1, discovered at Mitten Rock, New Mexico, in 1923, shows extensive pathological lesions of long standing. Nodules and depressions cover the entire vault. The trephined opening in the right frontal, immediately above the roof of the orbit, is roughly circular and includes the removal of most of the lower part of the bone. The lower left-hand border of the opening has invaded the right sinus frontalis. The opening is unusually large, measuring 40 x 50 mm. There are no evidences of healing. Considering the diseased nature of the skull it is probable that trephining was undertaken to relieve a long-established pathological condition. The right angular external process of the frontal shows evidences of a depression, indicating a depressed fractured area as the immediate cause of the operation. There are no marks of instruments beyond the sharply defined margins of the opening. Death doubtless ensued immediately after the operation. Shapiro thinks that the bone cut quite readily on account of its diseased condition. The skull is not artificially deformed, a rare condition in this archeological site where most skulls are deformed.² Shapiro regards the seat of operation as a dangerous one, but he does not say why. To my mind it is about as safe an area as any, but safety was not a

factor. The prehistoric surgeon was guided in his election by the depressed lesion, or by pain. It is interesting to note how

prevented artificial deformation. The individual seems to have reached the adult condition.

FIG. 1. Cranium found at Mitten Rock, New Mexico, by Earl H. Morris, during course of excavations in 1923, showing trephining by cutting method in right frontal. Opening measures about 40×50 mm. Lesion shows no evidence of healing. Pathological lesions and depressions occur on vault. Skull is not deformed.

skillfully the surgeon avoided cutting into the orbital cavity. The skull bones are quite thin, possibly due in part to the long-standing disease. This diseased condition may have originated in early youth and

The other skull (Fig. 2), discovered by Dr. Louis R. Sullivan at Lamy, New Mexico, at the San Cristobal ruins, is interesting because of a number of factors. Its undeformed dolichocephaly is in sharp contrast

FIG. 2. Incomplete trephined cranium discovered by Louis R. Sullivan in 1923 at Lamy, New Mexico. Borders of trephined opening are bevelled and cicatrized, indicating that healing had set in. Operation seems to have combined scraping and cutting. There are no accompanying pathological evidences and the reason why trephining was performed is not known. Long diameter of trephined opening is about 20 mm. Wavy line on left is sagittal suture. Cotton and gauze are, of course, recent. (Courtesy Dr. H. L. Shapiro, American Museum.)

to the other skulls which are compressed fronto-occipitally. This skull may represent a visitor from a distance or a member of an earlier and unknown race.

In this case (Fig. 2), trephining was in the right parietal, about 1 cm. from the sagittal suture. The opening is roughly diamond-shaped, measuring 20 mm. in long diameter. The regularity of the opening and the beveled edges reveal clearly the nature of the trephining. It was by cutting and scraping. The borders of the opening show healing, new bone has covered the diploic spaces exposed by the operation, and on the endocranial surface new bony growth is evident. There are no evidences of disease or injury and we do not know why the operation was undertaken. The patient undoubtedly survived the experience and died months later from an undetermined cause.

A comparison of the two trephined openings just described with those known from Peru reveals some distinctive characters. No trephine opening in Peru has

the same location, shape or extent as that depicted from Mitten Rock, New Mexico, (Fig. 1). Only one other example shows invasion of the frontal sinus, and that was a deliberate attempt to relieve sinus headache. The shape of the opening is unusual. We do not know how important these factors are. The other skull, from Lamy (Fig. 2) shows an operated site which was commonly used in Peru for practice postmortem operations. While all phases of surgery were practiced in ancient Peru, cutting, drilling, scraping, sawing, etc., the two trephined openings from the Southwest are largely by cutting, with scraping a secondary and uncertain factor. These facts do not tend to show any close interrelation between prehistoric New Mexico and pre-Columbian Peru.

BOOK REVIEWS

HUMAN BIOLOGY AND RACIAL WELFARE. Ed. by Edmund V. Cowdry, PH.D. 630 pp., illus. N. Y., Paul B. Hoeber, 1930.

One would have to be gifted in the art of using words and phrases and sentences to convey adequately to the reader the joy and solid pleasure in store for any person of education and understanding who begins reading this book. To me it read like a fast moving story written by a master. In fact, the book has been done by several master workmen.

Dr. Cowdry in his Preface, among other things, says: "The purpose of this book is to play a small part in breaking down these [extensive specialization] barriers in respect to the group of sciences which have a definite bearing on human welfare and are referred to collectively as "human biology."

The Introduction is by Edwin R. Embree. I read it twice. I would that I had space to quote from it at length. It would convince the

skeptic that here we have a book different yet more than worth while, a book not constructed for scientific men alone but for all who are commonly called educated. Embree begins his discourse and among other things says:

In an essay entitled "This Simian World" Clarence Day has considered what kind of planet this might be if some other species than the great apes had evolved into mastery. . . . We inherit some very great liabilities from these animal forebears. Our bodies are weak and puny as compared with the magnificence of elephants. . . . But we inherited in common with our monkey cousins, one great talent, namely curiosity. . . . Our chattering forebears have given us a love of talk. We are forever gabbling; we have invented great systems of languages; we even pay men to talk to us in groups. We store up words in scrolls and books, and build huge temples called libraries in which to hoard this preserved chatter. We compel children to devote years to the study of talk of previous generations. . . . We have also inherited a compulsion to action. We must always be busy . . . we rush about, we build and tear down and

build again. . . . Papers in the present volume discuss in fundamental terms various phases of the biology of man and his environment. Such presentation gives an approach to intelligent understanding of ourselves in our present state of development and in our present world.

The book is divided into five parts.

Part I is a chapter devoted to an essay on Life in Space and Time by Henry Norris Russell.

Part II has 6 chapters: Evolution Traced Biochemically, by A. B. Macallum; The Animal Ancestry of Man, by William K. Gregory; The Evolution of the Brain, by George H. Parker; Mental Evolution in the Primates, by Robert M. Yerkes; Societal Evolution, by W. M. Wheeler; Human Races, by Aleš Hrdlička.

Part III is composed of: The Vital Units Called Cells, by E. V. Cowdry; The Relation of Cells to One Another, by Alexis Carrel; The Integrative Action of the Vascular System, by W. B. Cannon; Nervous Integrations in Man, by J. F. Fulton and C. S. Sherrington; The Integration of the Sexes, by Clark Wissler.

Part IV covers: The Effects of Climate and Weather, by Ellsworth Huntington; The Reaction of Food, by Elmer V. McCollum; The Influence of Urban and Rural Environment, by Haven Emerson and Earle B. Phelps; Antisocial Behavior; Delinquency and Crime, by William Healy; Adjustment to Infectious Disease, by Hans Zinsser; What Medicine Has Done and Is Doing for the Race, by Sir Humphry Rolleston; The Relation of Science to Industry, by R. A. Millikan; The Influence of Education, by John Dewey.

Part V concludes the book with: The Inheritance of Disease, by Paul A. Lewis; Some Aspects of the Biology of Human Population, by Raymond Pearl; The Mingling of Races, by Charles B. Davenport; The Purposive Improvement of the Human Race, by Edwin Grant Conklin; The Intentional Shaping of Human Opinion, by H. A. Overstreet.

The Index is complete.

We list the subjects and authors feeling that this is the most impressive method of permitting the reader to reach his own conclusions; namely that this is a book more than worth while, a book human and absorbing and one of the truly important books of the year.

ELEMENTS D'INTERPRETATION RADIOSCOPIQUE ET RADIOGRAPHIQUE DES POUMONS. By Docteur, Loen Schekter, Boulogne-Sur-Mer, Paris, Doin, 1930.

In this little work the author claims that only the practicing physician can appreciate the full value of the radiological examination in the treatment of respiratory diseases. Without the x-ray examination, the clinical study is always incomplete and insufficient, but the radiographic study should not replace the clinical examination, or any of the other laboratory tests. A systematic screen examination should always be supplemented by films. An outline is given for the study of the diaphragm, the mediastinum, the esophagus and the parenchyma of the lungs and the points of differentiation between the various lesions.

While brief and sketchy, nevertheless the text serves to set forth the elements of interpretation, which is the author's object, as stated in the preface of the book.

A TEXTBOOK OF THE PRACTICE OF MEDICINE. Ed. by Frederick W. Price, M.D., F.R.S. (Edin.). Ed. 3. Oxford Univ. Press, 1929.

In almost 1900 pages of small type and thin paper there are the contents of a small "system of medicine." It is a pity that this work was not published in two volumes as the type and transparent paper make it very difficult reading (at least for the reviewer). Having stood the test, however, of three editions and six printings the book may be considered to have passed muster on its merits. There are twenty-six contributors who, to judge from the splendid literary quality of the work, have been chosen for their literary as well as their scientific abilities. As an up-to-date presentation of the practice of medicine, particularly from the British point of view, Price's textbook leaves little to be desired and the index of 110 pages is a model that other publications might well follow.

DIE CHIRURGIE DER BRUSTORGANE. Von Ferdinand Sauerbruch. Dritte Auflage, Erster Band, Die Erkrankungen der Lungen. Unter Mitarbeit von H. Alexander, H. Chaoul, W. Felix. Zweiter Teil. Chirurgische Behandlung der Lungentuberkulose Geschwülste der Lungen. Echinokokkus der Lungen Aktinomykose und Andere Pilzkrankungen der Lungen. Chirurgische Behandlung des Asthma Bronchiale. Syphilis der Lungen. Pp. 917-1373. Mit 189 zum Teil farbigen Abbildungen. Berlin, Julius Springer, 1930.

This part completes Volume I of Sauerbruch's classic, "Surgery of the Lungs." There are 189

illustrations, some of them colored, and all of them works of art. The detail in which the surgery of the lungs is taken up in this work is really a model for other publications. Though the book is not padded, a thorough test has found it answering every question that can be put to it. There is a bibliography of 146 pages and this is perhaps the best illustration that can be given of the interest in the subject. An expensive book, but one without which the armamentarium of anyone doing lung surgery is incomplete.

GASTRIC AND DUODENAL ULCER. By Arthur F. Hurst and Matthew J. Stewart, M.B. (Glas.), F.R.C.P. N. Y., Oxford Univ. Press, 1929.

Any book from the pen of Arthur F. Hurst is entitled to more than ordinary attention. A complete study of gastric and duodenal ulcer in which Dr. Hurst is assisted by Dr. Matthew J. Stewart, Professor of Pathology at the University of Leeds, is a publication of which every surgeon should take notice. This book of 544 pages with many illustrations and ten colored plates, unfortunately costs \$20.00, which makes the reviewer hesitate to make the recommendation he had in mind that "this book should be on the shelves of every practicing surgeon." It is, however, well worth the price for there is practically no question relating to gastric and duodenal ulcer that is not covered in this volume, beginning with an account of the earliest record of gastric ulcer reported in 1856 by Marcellus Donatus of Mantua and winding up with references to the latest cases reported. The authors and the

publishers have combined to produce, not only a valuable, but a beautiful book.

SYMPTOMS OF VISCERAL DISEASE. A Study of the Vegetative Nervous System in Its Relationship to Clinical Medicine. By Francis Marion Pottenger, M.D., LL.D., F.A.C.P. Ed. 4. 426 pp., 87 text illus. and 10 col. pl. St. Louis, C. V. Mosby, 1930.

A book that has gone through four editions may well be considered to have stood the test of time. Dr. Pottenger says in his Preface: "It has been my aim . . . not only to discuss the newer physiologic principles involved in the study of visceral neurology, but also to attempt to correlate them in such a manner as to make them readily applicable to clinical problems." This he has succeeded in doing. The book is well written, clear cut and authoritative. The illustrations are well selected and well executed. The bibliography makes no attempt at completeness, but covers all the essential references. It is a type of monograph of which there are all too few and every physician would be the better for a thorough study of this volume.

ORTHOPÄDIE IM KINDESALTER. Von Hofrat Prof. Dr. Hans Spitzzy, Wien, unter Mitwirkung von Geh. Hofrat Prof. Dr. Fritz Lange, München. 3. Vollig Umgearbeitete und Vermehrte Auflage. 510 pp., 253 illus. Leipzig, F. C. W. Vogel, 1930.

A well arranged monograph on surgical conditions met with in children, representing the best German teaching of the day. Profusely illustrated and well written, the book should be of interest to every orthopedist and pediatricist.

Subscribers to THE AMERICAN JOURNAL OF SURGERY visiting New York City are invited to make the office of the publishers (Paul B. Hoeber, Inc., 76 Fifth Avenue, New York) their headquarters. Mail, packages or bundles may be addressed in our care. Hotel reservations will gladly be made for those advising us in advance; kindly notify us in detail as to requirements and prices. List of operations in New York hospitals on file in our office daily.

A CLINICAL STUDY OF THE ABDOMINAL CAVITY AND PERITONEUM

SECTION I. THE CAVITY (*Continued*)*

E. INTRAPERITONEAL FLUIDS

Abdominal
Distention

IT has been taught, using an alliteration, that abdominal distention may be due to (1) fat, (2) flatus, (3) feces, (4) fetuses, or (5) fluids. With the exception of the fluids, these substances which cause abdominal distention are lodged either within the viscera or within retroperitoneal spaces. Fluids, upon the other hand, often accumulate within the peritoneal cavity proper, where they gravitate freely about over the inner surface of the membrane. Thus while the peritoneal cavity, anatomically speaking, is normally empty except for that small amount of serous moisture which serves to lubricate its surfaces, it is subject to invasion by pus, blood, urine, bile, chyle, enteral contents, cyst contents, amniotic fluid, transudates, exudates; and the belly, which has been described as a muscular bag, may suddenly be turned into an elastic bottle, as is implied by the term ascites (Gr. *askos*, a leathern bag, bladder or bottle).

Diagnostic
Problems

Free intraperitoneal fluids give rise to many diagnostic problems. Distention from fluids is not always easy to distinguish from that due to other causes. It is often difficult to differentiate free fluid from that which is encapsulated (tuberculous peritonitis), or from that which is present within some viscus (ovarian cyst, hydronephrosis); even an abnormal accumulation of some perfectly normal fluid presents diagnostic difficulties (distended bladder). After it has been definitely

* The study, thus far, has consisted of a consideration of the abdomen as an empty space and each of the abdominal boundaries: roof, floor, and walls, has been systematically investigated. Before proceeding to a study of abdominal viscera, two additional subjects will be reviewed concerning the cavity itself: (a) that of free intraperitoneal fluids, and (b) that of intra-abdominal pressures. Preceding installments have appeared as follows: January issue, p. 193; February issue, p. 460; March issue, p. 693.

determined that free fluid actually exists within the peritoneal cavity, the clinician must still seek to settle other important problems. What organ or tissue gives rise to the fluid and what type of pathological process causes the accumulation? Is it of recent origin (hemorrhage) or has it existed in the cavity over a more extended period (malignant peritonitis)? Is the fluid likely to increase in amount (bile peritonitis; chylous peritonitis) or to diminish (receding pyogenic infection); is it septic (pus) or sterile (blood); does its presence call for immediate action (perforated ulcer) or is the situation less urgent (Pick's disease, cirrhosis): Should the treatment be surgical (acute peritonitis) or non-surgical (Bright's disease, cardiac disorders); if surgical intervention is demanded, is the indication for paracentesis, incision and drainage, or for a more extensive procedure?

Before dealing with the technical manoeuvres employed to detect intra-abdominal accumulations and to determine their exact nature, and before studying the clinical pictures produced by different substances which invade the peritoneal cavity, it will prove advantageous briefly to review some points of anatomy which serve to explain the distribution of fluids within the cavity (intraperitoneal drainage basins). The clinician, as the operating surgeon, should be familiar with the exact manner in which a given fluid arising from a given source tends to spread more widely over the peritoneal membrane. It is only through an accurate visualization of anatomical arrangements beneath the surface and beyond the scope of the eye that the examiner is in a position fully to appreciate the mechanism by which certain diagnostic evidence is produced (Clark's sign, Toma's sign, shifting dullness, engorgement of superficial veins).

I. WATERSHEDS AND DRAINAGE BASINS OF THE PERITONEAL CAVITY. The drainage of liquids within the peritoneal cavity is governed, in greater part, by the same physical laws which determine the flow or accumulation of water in geographic areas. A watershed is defined⁷⁵ as a "ridge separating

Geological Basins

the head-streams which are tributary to two different river systems;" it is "a parting, or a divide;" the term refers to any inclination, whether a mountain crest or a gentle slope, which determines the separation of fluids as they enter different catchment basins. The catchment basins themselves are referred to at times as watersheds.

Human Basins

The surgeon, in studying the great partitions (watersheds) of the abdomen and the pockets (drainage basins) within the peritoneal cavity, is confronted by problems which do not beset the engineer. A human "geological map" represents structures which are movable, not fixed. Human barriers are subject to variations and displacements. Pockets which exist in the dorsal decubitus are different from those of a sitting or semi-sitting position, and of ventral or lateral decubitus. The posture of the patient has much to do with the area in which free fluid accumulates; the clinician must know where fluid is reasonably to be expected and searched for. Likewise, a close correlation must be maintained between the site of an incision for drainage and the postoperative position which is to be employed. It is important constantly to visualize the changes which occur in intra-abdominal contours as the patient is moved from one position to another.

Intraperitoneal Catchment Basins

A simple conception of the drainage basins of the peritoneal cavity is that these are four in number⁷⁶ (Fig. 53):

- (1). A supracolic basin
- (2). A right infracolic basin
- (3). A left infracolic basin
- (4). A pelvic basin.

These four spaces are determined by three great barriers or watersheds:

(a) The transverse colon and mesocolon which jointly divide the cavity into the supracolic and infracolic spaces.

(b) The vertebral bodies, aorta, inferior vena cava and mesentery of the small intestine (mesentery proper) which together serve to create the right and left infracolic basins.

FIG. 53. The four chief intraperitoneal drainage basins. (His' model.)
 A. Supracolic basin. B. Right infracolic basin. C. Left infracolic basin. D. Pelvis. (The stomach, liver, transverse colon, and small intestine have been removed.)

(c) The sacral promontory, acting with the psoas muscles and iliac vessels to separate the abdomen proper from the pelvis.

By another conception the cavity is considered to contain ten drainage basins, (A) five in the supracolic division, and (B) five below. These spaces are:⁷⁷

(A) Those above the transverse mesocolon.

(1) The omental bursa

(2) A subhepatic space

(3) A perisplenic space

(4) A right subphrenic space, separated by the coronary and falciform ligaments from

(5) A left subphrenic space.

(B) Those below the transverse mesocolon.

(6) The right infracolic space

(7) The left infracolic space

(8) The pelvis

(9) The right paracolic gutter (running with the long axis of the abdomen between the ascending colon and right parietal wall)

(10) The left paracolic gutter (running in the interval between the descending colon and the left parietal wall).

Further subdivision of the peritoneal cavity serves to introduce a confusing terminology and to pass beyond practical surgical fields into those which are more strictly anatomical.

Spreading
Peritonitis

The several abdominal drainage basins communicate more or less freely with one another (Fig. 54). For example, free fluid from a perforated gastric ulcer may first invade the subhepatic space or the omental bursa, then spread upward to the right subphrenic area, or again extend downward along the right paracolic gutter (there to simulate the peritonitis associated with a perforation of the appendix); it may even pass onward into the pelvis, and when sufficient accumulation has occurred, the fluid may well upward out of the pelvis to involve either subcolic fossa or to pass into the left paracolic

groove, to extend farther upward into the perisplenic space. A spreading peritonitis, as a spreading infection of the hand, travels onward by way of fairly fixed channels. But often this

FIG. 54. Spreading peritonitis. Communication of the "drainage basins" of the peritoneal cavity.

1. Subhepatic space. 2. Omental bursa. 3. Right subphrenic space. 4. Right paracolic gutter. 5. Pelvis. 6. Right infracolic space. 7. Left infracolic space. 8. Left paracolic space. 9. Perisplenic space. 10. Left subphrenic space.

spread may be checked in the space originally invaded, as further extension is anticipated through a proper placement

of drains. In speaking of abdominal infections as passing "upward" or "downward," authors refer to the anatomical or erect posture; but when patients assume some other position, these pockets or basins may no longer lie one above the other, but be on practically the same level, forming a single pool. (See Morison's space, p. 171.)

Anatomy of the
Perpendicular
Barrier

The Root of the
Mesentery

The position of the so-called "perpendicular barrier" is slightly oblique to the long axis of the body. The vertebral column and the large abdominal vessels follow the midline, but the mesentery of the small intestine (the mesentery proper) is attached in a line which runs from above downward in a direction which is slightly oblique and to the right. The root of the mesentery is approximately 6 inches long. While subject to some variation as to its obliquity and exact course, the point of origin is constant, being located at the duodeno-jejunal juncture at the lower border of the pancreas to the left of the second lumbar vertebra. Passing diagonally over the aorta, inferior vena cava, right ureter, and psoas major muscle, it reaches a variable point in the right lower quadrant. Free fluid to the right of the mesentery, therefore, is carried to the right lower quadrant of the abdomen, while that on the left passes into the pelvis. Hence, collections of blood and pus are much more frequently encountered in the right lower quadrant than in the left.

Anatomy of the
Transverse Barrier

The second great abdominal watershed or barrier is the transverse colon and its mesocolon. Above this partition, generally speaking, lie all of the solid organs: liver, pancreas, spleen, adrenals, kidneys, also the gall bladder and the gastric portion of the gastrointestinal tract; while below are found intestines only. In studying this barrier as a watershed, several points warrant special observation: (1) The root of the mesocolon is attached at the level of the first lumbar vertebra. It does not extend backward to the prevertebral fascia but overlies all of the other prevertebral structures (duodenum, pancreas, great vessels). (See section dealing with the rotation of the intestines for explanation of this arrangement.)

(2) It does not lie, as the name might imply, on a plane which is strictly transverse to the long axis with the cavity, but has a definite obliquity, due to the higher attachment of the left than of the right flexure of the colon. (3) The length of the transverse colon itself (19 to 20 in.) is nearly twice as great as the length of its mesentery. This barrier is, therefore, smooth only at its base and has deep waves and irregularities near its anterior margin. (4) The colon lies at a variable distance below the root of its mesentery, hanging at times in a v-shaped or u-shaped formation as low as the pelvis. Being attached to the stomach by the gastrocolic ligament, movements of the stomach and of the colon are necessarily somewhat similar and synchronous. (5) Due to the down hanging of the transverse colon on its mesentery, the barrier when viewed from the side has a sharp, though varying, obliquity which makes the highest part of the infracolic division of the peritoneal cavity actually higher than the lowest part of the supracolic division, i.e. the supracolic overhangs the infracolic compartment. (6) Anteriorly the barrier (transverse mesocolon) is sealed through a large part of its course by the gastrocolic ligament. Behind this ligament the barrier forms a part of the floor of the omental bursa (described with the gastrointestinal tract). Since the omental bursa is closed above, below, in back, in front and to the left, fluids can drain only to the right, or through the foramen of Winslow, passing into Morison's space (see p. 171). The portion of the transverse mesocolon to the right of the gastrocolic ligament is not anatomically sealed anteriorly, but the location of the transverse colon and the great omentum, directly in contact with the anterior abdominal wall, effectively prevents leakage to the general peritoneal cavity through this route. As previously noted, drainage is almost invariably to the right, extending downward to the paracolic groove. (7) The transverse mesocolon is wide only toward its center and to the left of the midline, while both extremities (near the right and left colic flexures) have either very short mesenteries or none at all,

being attached to the parietes only by areolar tissue. This is particularly true of the right side where the mesentery has appreciable width only after the left border of the head of the pancreas has been reached, i.e., almost at the midline of the body. (See transperitoneal removal of the kidney.) The practical application of these considerations will be referred to at many subsequent points in the text.

Morison's Space

2. SURGICAL DRAINAGE. With these intraperitoneal spaces freshly in mind it seems advantageous briefly to review the methods best adapted for securing adequate drainage of the cavity. A drainage basin of great importance is that known as Morison's space.⁷⁸ This consists of the subhepatic space, combined with the upper part of the right paracolic gutter. The space receives leakage from the gall bladder, the biliary ducts, the duodenum, and from a greater part of the stomach; in addition, it may form a basin for the extension of infections from pelvic organs or from the appendix, especially when the latter is retrocecal. The space, previously potential, is exposed by lifting the free border of the right lobe of the liver upward, away from the colon, after the abdomen has been entered through a right rectus incision. The upper wall of the space is composed largely of liver and gall bladder and it extends as far to the left as the opening into the omental bursa (foramen of Winslow), located at the right margin of the gastrohepatic omentum; it extends downward and backward reaching to the posterior abdominal wall, where the peritoneum stretches over the right kidney and duodenum; the lowest part of the space is bounded by the upper margin of the transverse mesocolon and the right flexure of the colon, but externally (to the right) it extends downward between the ascending colon and right parietal wall as far as the iliac crest; internally the space is bounded by the peritoneal reflexion covering the spinal column. A more detailed description of the space is given in the exact words of Morison in the section on Eponyms (p. 171).

The route for draining this space, as advocated by Morison, reaches the most dependent part of the area, both for the sitting

posture and the dorsal decubitus. The drain is introduced through the posterior parietes immediately below the lower end of the right kidney, i.e., just above the right iliac crest and below the extremity of the twelfth rib. The drain may be inserted through Petit's triangle, the base of which occupies from 1 to 2 inches of the iliac crest just posterior to its mid-point; or it may be passed through the muscles immediately posterior to this triangle. Internally the drain passes in front of the kidney and behind the liver, traversing the hepatorenal pouch, and extending upward to the region of the biliary ducts. This route for lateral and dependent drainage through the hepatorenal pouch may be visualized by *imagining* a 4 to 6 inch opening in the side of the body extending upward in the posterior axillary line from the iliac crest; the hand, slipped into this opening, would lie within the hepatorenal pouch as within a glove, the kidney behind, the right lobe of the liver in front (Fig. 55). Morison states that approximately a pint of fluid may be placed into this pouch before any spills into the general peritoneal cavity and that with lateral drainage through the route described it is even possible to drop the open gall bladder into the peritoneal cavity or to leave unsutured a large hole in the common or cystic ducts without causing generalized peritoneal contamination. Drains may be inserted into the hepatorenal pouch either from within outward or from without inward. During an abdominal operation the drain may be inserted under direct vision, or through palpating the depths of Morison's space as a small stab wound, thus controlled, is made in the parietes.

Drainage through
the Hepato-renal
Pouch

The biliary drain so often employed (a prophylactic wick in the subhepatic space) does not reach the lowest point of the hepatorenal pouch into which all leakage actually occurs. Such a drain may frequently, or even usually, prove adequate but it must be recalled that the drainage desired is not that of the ducts themselves, but of a basin into which the ducts leak. Thus there are times when simple subhepatic drainage may prove inadequate. This is evidenced in cases

where the discharge through the wound is profuse and seems adequate when judged by the degree of saturation of the outer dressings, but where a moderate upward pressure over

FIG. 55. Diagram showing relation of liver and right kidney; the hepatorenal pouch. The influence of respiration on the right kidney is also shown. A movement downwards of 1.5 cm. of the kidney may be regarded as the average amount in quiet respiration. (From Kelly and Burnam's "Diseases of the Kidney, Ureters and Bladder," D. Appleton.)

the outer side of the ascending colon will cause a large quantity of residual fluid to well forth from the incision. With such definite evidence of inadequate drainage a secondary drain may be inserted through the lowermost part of Morison's space.

The right infracolic space, when viewed from the front, presents a triangular appearance, due to the obliquity of the

mesentery of the small intestine. The base of the triangle consists of the inferior leaf of the transverse mesocolon; the right limb is formed by the ascending colon and cecum; the left limb of the triangle consists of the right side of the mesenteric root. The upper, outer angle is formed by the right colic flexure; the upper inner angle is the spinal column at the level of the second lumbar vertebra, and the inferior part of the duodenum crossed by the superior mesenteric vessels; the lower angle, or apex of the triangle, approaches the cecum and vermiform appendix, but remains partly open, providing a narrow communication into the pelvis. The inferior third of the right kidney may be palpated and examined below the right colic flexure in the upper, outer angle of the triangle. To inspect the right infracolic space thoroughly the coils of small bowel lying within the area should be moved en masse downward and to the left,⁷⁹ i.e., displaced upon their mesenteric hinge. The right infracolic space is drained either through the anterior abdominal wall, or through the lateral wall, the drain in either case being carried to the center and depths of this basin. (See Fig. 53.)

Drainage of the
Right Infra-Colic
Spaces

The left infracolic basin is bounded superiorly by the left third of the transverse mesocolon, medially by the vertebral column and left leaf of the mesentery, laterally by the descending and sigmoid colon. The shape is not so definitely triangular, since inferiorly there remains a wide and direct communication with the pelvis. The left kidney is palpable within this basin, lying beneath the left colic flexure. The duodenojejunal juncture is located at the upper, inner angle of the space. The left infracolic space reaches a higher level than the right infracolic space, due to the high fixation of the right flexure of the colon (the obliquity of the transverse mesocolon). (See Fig. 53.) To examine this drainage basin the coils of small intestines may be displaced upon their mesentery upward and to the right. The left infracolic space is drained either directly or through the pelvis, the pouch of Douglas in the female and the rectovesical pouch in the male, as discussed later.

Drainage of the
Left Infracolic
Space

Pelvic Drainage

Pelvic drainage may be secured through a suprapubic incision, an incision in either lower abdominal quadrant, through the vagina, the perineum, or through the rectum.

FIG. 56. Posterior colpotomy for drainage of pus which has gravitated to lowest portion of peritoneal cavity. Penetrating abscess wall. The sharp-pointed scissors, under the guidance of the finger, have been introduced into the mass and then opened widely. (From Crossen's Operative Gynecology, C. V. Mosby Co.)

In instances of diffuse or spreading peritonitis and when an abdominal incision is already present, drainage is usually accomplished from above. But a favorite method for the drain-

age of a chronic pelvic abscess in a female is to enter the pouch of Douglas by way of the posterior vaginal wall (posterior colpotomy) (Fig. 56).

FIG. 57. Stab wound drains: (a) to the pelvis; (b) to the right infracolic space; (c) to the right paracolic gutter. These three drains might all have been brought to the surface through the operative wound. (From Royster's "Appendicitis," D. Appleton.)

A consideration of methods for practical drainage of infectious material from individual abdominal organs may serve as a review of the drainage basins and their communications:

Appendix. Operations of the "interval" type and for a subacute or non-perforative variety of appendicitis may be concluded without drainage. In the presence of a moderate leucocytosis or slight localized peritoneal exudate it may prove wise to carry a "prophylactic" wick to the site of the appendicular stump in the right subcolic fossa. A retrocecal abscess may be drained through the loin or by passing a drain from the anterior wound to the right paracolic gutter. In the presence of a spreading or diffuse peritonitis three drains may be utilized: one to the right paracolic groove, one to the right infracolic fossa, and one into the depths of the pelvis (Fig. 57).

Drainage of Individual Organs

Gall Bladder. Drainage of this organ both through the abdominal (ventral) wound and through the hepatorenal pouch, has already been discussed.

Duodenum. Leakage from most duodenal perforations occurs into the subhepatic portion of the supracolic division of the abdomen and there may be drained through the ventral wound, but preferably through the route of Morison (hepatorenal). The peritoneum takes care of duodenal leakage in a remarkable fashion providing the perforation is promptly and adequately closed. Leakage into the omental bursa may be drained as later described.

Stomach. Perforations of this organ may involve the subhepatic space (usual), the omental bursa, the perisplenic area (rare) or the general peritoneal cavity. The omental bursa empties into the subhepatic space through the foramen of Winslow and may be drained as described in the discussion of Morison's space. It may also be drained through an opening in the gastrocolic ligament, through the great omentum, or from below through the transverse mesocolon. The perisplenic space may be drained by means of a wick carried directly to the depths of this basin, either through a high left paramedian incision or a stab wound in the left parietes; such drainage may or may not be associated with drainage of the left paracolic gutter.

Spleen. (See perisplenic space).

Pancreas. Drainage may be established through the omental bursa (by any of the several routes described), through the left posterior parietal wall (retroperitoneal extravasations), or through the cystic duct (cholecystostomy for pancreatic congestion).

Pelvic Organs. (Previously described.)

Kidney. Perirenal infections may be drained retroperitoneally by means of an incision in the posterior or lateral parietes.

Bladder. The space of Retzius may be drained (retroperitoneal drainage) suprapubically through the midline alone or through multiple incision.

Subphrenic Abscesses. (See chapter dealing with the diaphragm.)

Just as gravity plays a great part in determining the site at which pus and other fluids will accumulate, so it also plays an important (though by no means the only) rôle in securing effective drainage. The pelvis is fittingly termed "a basin," not only on account of its shape but also because when patients are placed in the upright or the semisitting posture (Fowler position) fluids gravitate to this cavity; the most dependent point at which to drain the pelvis is through the pelvis floor. The space of Morison is reached at its lowest point by way of the hepatorenal pouch (route of Morison). The perisplenic space is given dependent drainage through inserting the wick into the lowest part of the left paracolic gutter to which perisplenic abscesses tend to gravitate. The left subcolic space is often adequately drained only when the drainage material has also been carried into the pelvis. The value of the Fowler position in diminishing the spread of septic material throughout the peritoneal cavity and in minimizing absorption will be more fully discussed in the section dealing with the peritoneal membrane. Placing a pillow beneath the left hip and shoulder may aid in securing drainage when there is an incision in the right loin, and a similar support or elevation of the right side of the body aids in securing drainage to the left.

Influence of Post-operative Posture on Drainage

When the original incision is made at a site other than that which gives dependent drainage it is often advantageous to place a secondary drain through a stab wound at the desired site. Small stab wound incisions may be easily, safely and bluntly made under the guidance of the hand within the abdomen. In addition to yielding the maximum advantage from position such secondary wounds prevent the pus from soaking the main operative wound and thus reduce the likelihood of wound infection and subsequent hernia formation.

3. METHODS FOR THE CLINICAL DETECTION OF FLUIDS. The clinician uses special technical terms in referring to

A Special Terminology

abnormal fluid collections throughout the body. *Dropsy* signifies either an extensive and marked "water-logging" of the entire system such as is observed with certain cardiac and renal disorders, or a more localized morbid accumulation of watery liquid within some cavity or within the tissues themselves. The term *hydrops* (an abbreviation for Gr. water + dropsy) literally means the same, but in ordinary clinical usage indicates a watery collection within some special organ or space, as *hydrops vesicae felleae* (an accumulation of clear, or non-bile-stained fluid within the gall bladder) or thoracic *hydrops* (a pleural effusion).

Anasarca (Gr. *ana*, through + *sarx*, flesh), like the word dropsy, means a generalized infiltration (a seepage throughout the flesh) of thin, clear, or watery fluid. Any cystic swelling containing serous fluid is termed a *hygroma* (Gr. water + tumor, for example a housemaid's knee or a compound ganglion the wrist). The term *edema* (Gr. swelling) implies a puffiness at due to the choking of the areolar tissues and interstices of the involved part by abnormal amounts of liquids. The word *fluid* itself (L. *fluidus*, flowing) signifies the presence of a substance which is non-resistant, non-solid, or mobile, hence the term *effusion* (L. *e*, out + *fudare*, to flow) suggests quite a different pathological process from that of *exudation* (L. *e*, out + *udare*, to sweat, or produce in beads). An effusion is a rapid outpouring of thin liquid while an exudation is a more laborious liberation of a thick, viscid, or more organized substance. The derivation of the term *ascites* has previously been referred to (Gr. *askos*, a water bag).

Laws Regarding
Fluids

Fluids within the body, as fluids elsewhere, possess typical characteristics and are governed by laws which are peculiar to themselves.

a. Fluids are particularly weighty (1 cu. ft. of water weighs about 1000 oz., 28.5 kg., or roughly 63 lb.), and the total weight of the body is largely due to the fluid which it contains. This fact readily explains why a patient with cancer who has undergone, or reasonably should have undergone, a considerable

loss of weight may suddenly acquire new weight with the onset of ascites or dropsy; and since water is over 700 times heavier than air, a hydrocele may often be differentiated from an enterocele by simply picking up the mass within the palm, in order to estimate its specific gravity.

b. Water is a poor conductor of heat and when the fluids of edema block the tissue spaces, obliterating superficial blood vessels, the involved part may seem abnormally cold. The temperature of a boggy extremity gives no fair index as to the condition of its deep arterial supply and the vascular efficiency is better estimated through palpating the peripheral pulse or through taking the temperature of a non-edematous portion such as the toes or fingers; again, in the early stages of an acute inflammatory process the local temperature appears elevated but after a large collection of pus has formed the temperature may actually seem lowered, while an incision carried through edematous tissues overlying an abscess may show the boggy area itself, even though cold, to contain pus.

c. Fluids are substances incapable of resisting forces; they follow pathways of least resistance; while a solid possesses both size and shape, a liquid has size but not shape. As already discussed free fluids within the peritoneal cavity move about, flowing along the watersheds and into the catchment basins under the influence of gravity. Free fluids seem to "swish" or yield in a perfectly characteristic fashion beneath the examining hands.

d. Fluids are almost totally incompressible (under a complete additional atmosphere of pressure water is condensed by only 1/20,000 of its bulk). Intestines filled with fluid, then, are far more likely to be ruptured by a sudden force such as a kick than are those filled with gas; similarly, the empty or semi-empty bladder is ruptured with difficulty, while the distended bladder may burst from comparatively slight trauma.

e. Bodies immersed in fluid must displace their own bulk (Archimedes' principle). Hence the patient with respiratory

and cardiac embarrassment due to a marked ascites will suffer from additional discomfort after eating, especially when the food is poorly selected as to bulk; conversely, the removal of a copious liquid or formed stool will reduce the pressure within the abdomen and within the ascitic fluid itself.

f. Any additional pressure exerted upon an enclosed fluid mass is transmitted equally in all directions (Pascal's law). A venous varix in the femoral region may be differentiated from a femoral hernia by simply tapping upon the associated varicose veins of the leg while testing with the opposite hand over the mass for a transmitted fluid wave. Again, when a marked ascites is associated with an umbilical bulge, tapping at almost any point on the belly wall will be followed by a perceptible movement or expansion within the umbilical nodule. It follows from Pascal's law that no sustained tangential pressure can be exerted through a fluid mass. Lateral pressure over an abdomen distended with fluid will transmit to the opposite side a momentary impulse or "a fluid wave" but lateral pressure along this tangent is never sustained since the force is immediately distributed equally in every direction. This dissipation of pressure often serves to differentiate a fluid mass from a solid mass, for a tumor frequently may be pushed about or rocked from side to side.

The clinical picture caused by free intraperitoneal fluid will depend to a considerable extent upon the amount of fluid present, i.e. whether the quantity be marked, moderate or slight.

(1) *When the accumulation is marked* the findings are as follows (Fig. 58):

**The Physical
Examination**

Inspection reveals a typical picture.

The abdomen is symmetrically distended.

The belly appears globular or barrel-shaped.

The skin is tense and glistening; striae may be present.

The umbilicus is prominent or protruding.

The intercostal angle is widened; the lower ribs bulge; the abdomen is out of all proportion to the thorax as a whole.

The abdominal respiratory movements are diminished or absent.

The legs, thighs and scrotum may be edematous.

FIG. 58. General enlargement of the abdomen from abdominal dropsy (ascites). (From Anders' "Physical Diagnosis." D. Appleton and Co.)

Hernial weaknesses in the walls bulge and are filled with fluid.

The superficial veins may be engorged; congestion of the hemorrhoidal and pampiniform plexuses and a complete or partial caput Medusae are sometimes present.

Palpation. A fluid wave or thrill is present; this does not disappear as pressure is made upon the anterior abdominal wall.

Percussion at any point yields a visible enlargement of palpable thrill within the protuberant umbilicus.

Dipping or ballottement may be detected where a solid tumor or enlarged liver underlies fluid.

The cardiac impulse may be displaced upward, or upward and slightly to the left.

The abdomen feels tense and characteristically weighty; this tension and peculiar resistance are most marked in the bulging flanks.

Percussion. The flanks and suprapubic regions are flat or dull or the dullness may be generalized.

Tympany, if present, tends to be central in location.

Mensuration. When the patient is erect the greatest circumference is that of the hypogastrium.

When the patient is in the dorsal decubitus the umbilical circumference is greatest (measurements taken through the umbilicus anteriorly and the tip of the spine of the third lumbar vertebra posteriorly).

The umbilicus retains its normal central position (not elevated as with a gravid uterus or distended bladder). (Measurements are made from the umbilicus to the symphysis pubis and from the umbilicus to the sternoxiphoid junction.)

With the patient lying flat on the back the umbilicus also retains a central alignment (not displaced to the side as with ovarian cyst). (Measurements are made from the umbilicus to each anterior superior iliac spine.)

Horseshoe-shaped
Area of Dullness

(2) *When the Accumulation is Moderate.* The distention is still symmetrical and tends to be globular or barrel-shaped when the patient is sitting or erect. When the dorsal decubitus is assumed, however, the flanks bulge while the central area of the abdomen appears flattened. To the typical fluid wave sign is added a second valuable phenomenon, i.e. that of shifting dullness (Fig. 59). (The level of the fluid in the flanks shifts as the patient turns to the side.) The suprapubic line of dullness, when the patient is in the dorsal decubitus, is curved with the concavity directed centralward (Fig. 60).

(3) *When the Accumulation is Slight.* If the fluid is minimal in amount it may be lodged entirely within the infracolic spaces as the patient lies flat, or in the pelvis as he sits

FIG. 59. Shifting dullness: evidence of free intraperitoneal fluid.

or stands. The inability to demonstrate small amounts of fluid is not absolute proof of the absence of free fluid from the cavity. The best means for detecting a small amount of fluid is to turn the patient well upon his side and attempt to demonstrate shifting dullness in the dependent flank or to place him, should his condition warrant, in the knee-elbow position and search for a flat or dull note about the umbilicus. The per-

cussion should be very light in character, for only by this method may a thin layer of liquid overlying tympanitic bowel (small amount in paracolic gutter) be detected.

FIG. 60.

A. Distention with ascites. Note distribution of fluid with central curved line of dullness.

B. Distention with ovarian cyst. Note that maximum distention is below the umbilicus and that there is no extension to the flanks. (From Douglas.)

Special Rules. In examining the abdomen for free fluid the following general rules should be borne in mind:

(1) The abdomen has not been completely examined until the posterior as well as the anterior wall has been palpated and until in the male the rectum and in the female both the rectum and the vagina have been explored digitally. By making rectal and vaginal examinations a routine part of an abdominal examination many diagnostic blunders may be avoided, and some of these blunders may be safely avoided in no other manner.

(2) The abdomen should be reexamined after catheterization, the administration of enemas, paracentesis, operations, or partial recovery under conservative treatment; questions may then be answered which could not be settled until the intra-abdominal pressure had been reduced.

(3) The examination of the abdomen alone is often insufficient; other parts of the body should also be studied before attempting a final diagnosis.

(4) Here as elsewhere the well-taken history is the safest guide to an accurate diagnosis and this should always be correlated with the findings upon local examination.

It is often easy to state the precise cause for the intra-peritoneal fluid but there will remain instances in which it will prove impossible, without entering the abdomen to perform an operation or autopsy, to name the primary condition with precision.

Most important of the special evidences of fluid are the signs of dipping, ballottement, shifting dullness, the fluid wave, venous engorgement, and reducible hydrocele.

The tests known as "dipping" and "ballottement" both depend upon the presence within the abdomen of some solid mass as well as free fluid. When an enlarged liver or a solid tumor lies beneath a layer of free fluid it may sometimes be palpated by suddenly pushing the tips of the extended fingers of the examining hand against the anterior or lateral abdominal wall (dipping). The mass is "bumped against" in a characteristic fashion; and as the fingers are withdrawn the fluid flows back again to cover the tumefaction (Fig. 61). Once felt this sensation will not be forgotten. It is a pathognomonic sign of fluid. The same sensation is gained in palpating the patella after compressing with the fingertips a prepatellar bursa moderately filled with a serous effusion. When, during an abdominal examination, an enlarged liver has been detected and a moderate amount of free fluid is thought also to be present, the demonstration of dipping after the patient has been placed in the Trendelenburg position proves the presence of the free fluid.

Dipping with
Ascites

Ballottement

True ballottement (Fr., *balloter*, to toss up) is a sign used in the diagnosis of pregnancy. Here, with the tip of the fore-finger in the vagina a sharp tap is made in the lower segment

FIG. 61. "Dipping" with ascites. To palpate the liver: one quick jab in direction of arrow. (After Slade.)

of the uterus; the embryo, if present, is tossed upward and if the finger is retained in place will presently be felt to strike against the wall of the uterus as it falls back. Or, as the pregnant uterus is pushed against from the side, the fetus may be displaced within the amniotic fluid, only to float back and impart a gentle tap against the examining hand which has been held quietly in position. A solid mass, particularly if supplied with a pedicle will often impart the same sensation to the examining fingers as it floats back to an original position after being displaced.

The Fluid Wave

The fluid wave has been discussed with the mention of Pascal's law and of the inability to maintain a sustained tangential pressure through a fluid medium. The sensation experienced upon tapping against an ascitic abdomen (the abdomen then being by definition an elastic bottle) may be duplicated by tapping against a rubber waterbottle and detecting with the opposite hand the characteristic fluid wave. To make the fluid wave test as the patient is attempting to

rise without the use of his arms from the recumbent to the semirecumbent posture will enhance the ease of its detection.⁸⁰ This manoeuvre by contracting the abdominal muscles increases the pressure upon the ascitic fluid. By conducting the test after this special manner even small amounts of free intraperitoneal fluid may be demonstrated.

Shifting dullness is illustrated in accompanying photographs (Fig. 59). When the fluid is considerable in amount the shift of the line of flatness or dullness may be considerable, but the error is frequently made of expecting too great a shift when the amount of free fluid is small. So great is the capacity of the peritoneal cavity that the addition of even a quart of fluid to any given amount raises the total level but little as the patient lies flat upon the back. The repeated demonstration of even one fingerbreadth of shifting dullness constitutes reliable evidence of free fluid. It has been pointed out (Mayo-Robson) that when the free fluid consists of blood the shifting in the flanks takes place slowly, due to the fact that some of the blood is clotted and semigelatinous. Hence sufficient time should be allowed, when testing, for the complete shift to take place (in the case of blood a full minute) and when the shift is definitely demonstrated and proved to be unusually slow, the evidence points to a fluid which is thick and presumptively blood.

Shifting Dullness

The venous engorgement may be due to the same cause which is exciting the free fluid (retroperitoneal tumors, cirrhosis) or it may be due to the weight of the fluid alone as it presses upon veins such as the iliac, inferior vena cava, or those of the portal system. The typical caput Medusae has already been described. At times only a few longitudinal superficial veins or even a single vein may be seen upon the distended anterior abdominal wall (see Fig. 58). The vein or veins extend upward from the umbilicus, carrying blood which would normally be passing to the heart by way of the portal vein but now has come to the surface through the veins reaching the umbilicus along the round and falciform ligaments of the liver and by a collateral route is passing through the

Superficial Venous
Engorgement

paraumbilical veins to reach the internal mammary veins or those associated with the diaphragm and ultimately the superior vena cava (Fig. 62). With obstruction to the inferior

FIG. 62.

vena cava they may pass upward from the thighs, traversing the entire anterior abdominal wall to reach the heart from above, chiefly by way of the thoracoepigastric veins, to reach the superior vena cava through the axillary and subclavian veins. The veins of this latter route (Fig. 62) have been termed the "caval" veins (collaterals from the inferior vena cava). It has been pointed out⁸¹ that when both sets of veins are involved, due to ascites associated with disorders of the liver (carcinoma, cirrhosis), a withdrawal of the ascitic fluid by

The "Caval" Veins

FIG. 62.

11. The superficial abdominal veins. A. "Portal group." B. "Caval group."
(From Spalteholz.)

paracentesis, thus removing the weight from the inferior vena cava, may result in a disappearance of the caval veins while the portal collateral veins remain distended, thereby demonstrating the persistence of the obstruction to the portal vein by the primary pathological process.

Reducible
Hydrocele

Ascitic and other free intraperitoneal fluids gravitate into prolongations of the peritoneal membrane (hernial sacs) when these are dependent in position. In the inguinal region such a condition is known as a reducible hydrocele. The presence of an open hernial sac may, indeed, prove a valuable aid in the demonstration, by appropriate posture, of a small amount of free fluid, and when the sac is otherwise empty the fluid, under strict aseptic precautions, may safely be withdrawn for identification.

4. DIFFERENTIATING THE CAUSES OF ABDOMINAL DISTENTION. It is usually though not always easy to distinguish free intraperitoneal fluid from other conditions causing abdominal distention. Aside from the positive methods of identification discussed, certain general "negative" evidence will prove of value.

a. Distention due to fat is characterized by a generalized thickening of the panniculus adiposus throughout the body (face, neck, extremities, buttocks); the abdomen retains its normal relative size to that of the thorax. The panniculus may be picked up between the fingers and the superficial nature of the condition demonstrated. It must be recalled, however, that with excessive subcutaneous fat there will also be a weakening of abdominal supporting walls due to fatty infiltration and that intra-abdominal fat also will be excessive. The suggestion of a fluid wave observed in the corpulent patient disappears as the "fat wave" is blocked by the margin of an assistant's hand pressed firmly against the linea alba. In some instances excessive fat and ascitic fluid will coexist within the abdomen, yielding distention of a dual nature.

b. Distention due to flatus tends to be localized, is associated with marked tympany and often with visible peristaltic waves

seen upon the anterior abdominal wall or initiated by flicking the abdomen with a moist towel or snipping it with the fingertips. When the large bowel is the seat of distention with gas,

FIG. 63. Distention due to flatus.

- A. Diagram to show appearance of moderate distention of the large gut.
- B. Drawing to show ladder pattern of abdominal distention (indicating obstruction of the lower ileum). (From Cope.)

proximal to a rectal or sigmoid obstruction, the distention is found at the periphery of the abdomen (Fig. 63A). When the gas is restricted to small bowel the distention tends to be central in location and to display a typical "ladder pattern" (Fig. 63B). When the stomach is acutely dilated the swelling lies to the left of the midline and is umbilical or subumbilical in location while the epigastrium is largely uninvolved. The stomach pump or the rectal tube may prove of service in establishing the diagnosis.

c. *Distention due to feces* is nodular or patchy; the asymmetry is obvious; and the cause of the condition may be demonstrated by cleansing the gastrointestinal tract. Rectal

examination will often reveal impacted feces or some obstructive lesion in the lower bowel. A succussion splash may be obtained when gas and liquid coexist in colon or stomach.

FIG. 64. Abdominal distention due to gravid uterus and distended bladder. (From DeLee's "Principles and Practice of Obstetrics." W. B. Saunders Co.)

d. Distention due to a gravid uterus should present little diagnostic difficulty. There is a history of the cessation of menses and the vaginal examination may reveal ballottement and softening or congestion of the cervix. Externally, fetal movements, fetal heart sounds, or a funic souffle often are detectable (Fig. 64). A fetus may be identified by a roentgenogram as early as the fifth month.

e. Distention Due to Solid Tumors. Solid tumors often cause or are associated with ascites. Means for identifying and differentiating various solid tumors are discussed elsewhere (section on the Solid Organs). When tumors are present, unassociated with ascites, the distention tends to be asymmetrical; dullness is lacking in the flank, the presenting mass

has form as well as size; it may be movable or move spontaneously with respiration; and its surface and consistency may serve to identify the swelling. With intra-abdominal malignancies there may be enlargement of the left supraclavicular gland (so-called Troisier or Virchow-Troisier gland).

Distention due to localized collections of fluid tend to displace the umbilicus upward, downward, or lateral; although the mass is dull the flanks are tympanitic; no typical shifting is observed; the swelling is usually ovoid in form and can often be easily outlined. Distended bladder disappears with catheterization (see Fig. 64), the hydronephrotic tumor tends to vary in size, in association with a history of polyuria; the ovarian cyst springs from or begins in one side and frequently may be identified by the pelvic examination.

SECTION OF SURGERY.

W. MITCHELL BANKS, M.D., F.R.C.S., President.

THE ANATOMY OF THE RIGHT HYPOCHON-
DRIUM RELATING ESPECIALLY TO OPER-
ATIONS FOR GALL STONES.

By RUTHERFORD MORISON, M.B., F.R.C.S.,

Senior Assistant Surgeon, Royal Infirmary, Newcastle-on-Tyne.

THE purposes of my paper are: 1. To draw attention briefly to the anatomy of the parts concerned in the surgical treatment of gall stones, with the object of demonstrating that a pouch exists behind the right lobe of the liver which has natural barricades separating it from the general peritoneal cavity. 2. To suggest that efficient drainage of this pouch is likely to serve a useful purpose in gall stone operations.

If the abdomen be opened in the right linea semilunaris, the sharp lower border of the right lobe of the liver, with frequently the fundus of the gall bladder, will be seen resting against the transverse colon. If the edge of the liver be drawn upwards and the colon downwards, a space, previously potential, is exposed (Fig. 1). The roof or anterior wall which has just been opened up is not sealed. It looks forwards and to the right. From right to left it is formed by the peritoneum covering the diaphragm, the under surface of the right lobe of the liver, and the gall bladder, and not unusually is completed internally by a fold of the gastro-hepatic omentum continued to that viscus.

The floor is formed by the ascending mesocolon covering the kidney, duodenum, and other structures lying on the posterior abdominal parietes (Fig. 1). Superiorly the space is bounded by the right lobe of the liver. Inferiorly by the ascending layer of the transverse mesocolon (Fig. 2), covering the duodenum internally. Externally by the peritoneum lining the lumbar parietes as far down as the iliac crest. Internally by the peritoneum covering the spine behind, the free edge of the gastro-hepatic omentum in front, and the foramen of Winslow between the two (Fig. 3).

This pouch can be effectually drained by an opening made through the posterior parietes immediately below the lower end of the kidney, for the remaining dependent part is occupied by the right end of the right lobe of the liver. A varying quantity of fluid, roughly a pint, may be introduced into the pouch from below before any overflow into the general peritoneal cavity can take place. The fol-

Fig. 1.—The pouch described shown by drawing liver upward. X in all the figured marks points for drainage.

CONCLUSIONS.

A pouch exists below the right lobe of the liver and gall bladder separated from the general peritoneal cavity by natural barriers. This pouch can be efficiently drained through an opening in the parietes near the lower end of the kidney. A transverse is better than a vertical incision in operating for gall stones; less likely to be followed by ventral hernia and giving free access. Biliary fistula results from operations for gall stones in a considerable percentage of cases in which the gall bladder has been attached by sutures to the parietes. The method of attachment has little to do with this result and it may follow when the ducts are patent. The gall bladder and ducts may safely be allowed to empty into the pouch described, if it is properly drained. The gall bladder should never, except when suppurating, be stitched to the abdominal wall. If the pouch is properly drained (a) when the gall bladder is distended, the opening in it should be closed by sutures and the viscous returned into the abdominal cavity and the drain left until the certainty of its successful closing is complete. b. When the gall bladder is shrunken and there is difficulty in closing the opening made in it, it may be returned unclosed. c. When a stone is impacted in the cystic duct and evades all ordinary efforts to remove it the gall bladder should be excised and the duct ligatured after removing the stone in it. d. When a stone is impacted in the common duct, the duct is incised and after the stone or stones are removed the opening may be left unclosed if there is any difficulty in applying a satisfactory suture.

(c) *Pain and Tenderness.*—These symptoms, although important when present, are so variable that even their complete absence is no proof that the pancreas is normal. Both pain and tenderness are, as a rule, absent in malignant disease of the head of the pancreas, but in exceptional cases of carcinoma and sarcoma of the head, body, or tail the pain may be excruciating. This is due either to pressure on, or involvement of, the great sympathetic ganglia, or to pressure on, or invasion of, neighbouring viscera, particularly the stomach and duodenum. Small scirrhous tumours are, as a rule, characterised by absence of pain, while large growths are often marked by constant and extreme agony. In the various forms of pancreatitis pain and tenderness in the epigastrium are generally well marked. The more acute inflammations are characterised by excessive tenderness on pressure, the presence of a tender spot just above and to the right of the umbilicus, rigidity of the recti, and pain of an agonising character. The pain in hæmorrhage into the pancreas is intermittent, being at times severe and of a colicky character, then diminishing or disappearing, to return later with increased intensity. In chronic pancreatitis pain and tenderness, although usually present, may be but little marked. In

ness are pronounced. Calculus of the pancreas may exist for years undetected, and unsuspected, without causing any pain. If, however, the calculus reaches the orifice of the pancreatic duct, or is impacted in the ampulla of Vater, severe paroxysmal pain, resembling a gall-stone seizure, will occur and be associated with jaundice. As to the character of the pain, it may be continuous or paroxysmal, and may be limited to the epigastrium or radiate around either side of the thorax. Pain in the back, under the left scapula, or between the scapulae, is more frequent than pain beneath the right scapula in pancreatic disease, thus serving to distinguish it from gall-bladder pain. "Coeliac neural-

| Discussion of Eponym : | While it has been known since the time of Virchow that a tumefaction of the supraclavicular ganglia might be caused by cancer of the stomach, Troisier made a most complete study of the subject and showed that the adenopathy might occupy either side of the neck or both sides at once, but that the left side was the favorite site. He showed also that the left supraclavicular gland involvement might be due to any abdominal cancer whatever (pancreas, liver, kidneys, uterus, testicles, ovaries). From the time Troisier wrote his medical thesis the subject of cancer of the lymphatic glands and vessels was "dearest to his heart," and he wrote many articles concerning his researches in this field. |

A TRANSLATION OF THE FIRST OF A SERIES OF PAPERS BY TROISIER RELATIVE TO ENLARGED SUPRACLAVICULAR GLANDS WITH INTRA- ABDOMINAL CANCER

THE SUPRACLAVICULAR GLANDS IN CANCER OF THE STOMACH

It is well known that cancer of the esophagus and that cancer of the lung are rather often propagated to glands of the lateral and inferior parts of the neck and this localization is justly considered as a valuable sign for the diagnosis of a cancer within the thoracic cavity. It must not, however, be believed that propagation to the supraclavicular glands occurs only in cancer of the esophagus at its upper part and in cancer of the pleura or of the lung. I propose to prove that it exists in cancer of the stomach. I do not need to state that this propagation is absolutely exceptional.

When M. Charcot was president of the Anatomic Society, I had often heard him say that Henoch in his "Clinique des maladies du bas-ventre," had pointed out propagation of cancer of the stomach to the glands of the supraclavicular cavity (see in particular the Bulletin of the year 1876, page 460). Thus it is that my attention was drawn to this point and since that time I have never neglected to look for this propa-

LES GANGLIONS SUS-CLAVICULAIRES DANS LE CANCER DE L'ESTOMAC, par M. TROISSE, agrégé, médecin de l'hôpital Saint-Antoine.

I. On sait que le cancer de l'œsophage et que le cancer du poulmon se propagent assez souvent aux ganglions de la partie initiale et inférieure du cou, et l'on considère à juste titre cette localisation comme un signe précieux pour le diagnostic d'un cancer de la cavité thoracique. Il ne faudrait pas croire cependant que la propagation aux ganglions sus-claviculaires ne puisse se rencontrer que dans le cancer de l'œsophage et sa partie supérieure et dans le cancer de la plèvre ou du poulmon. Je me propose de prouver qu'elle existe dans le cancer de l'estomac. Je n'ai pas besoin de dire que cette propagation est tout à fait exceptionnelle.

Lorsque M. Chirac était président de la Société anatomique, je lui avais

souvent entendu dire qu'Hennoch, dans sa *Clinique des maladies du bas-ventre*, avait signalé la propagation du cancer de l'estomac aux ganglions du creux sus-claviculaire (voy. en particulier les *Bulletins* de l'année 1874, p. 160). C'est ainsi que mon attention a été attirée sur ce point, et depuis cette époque je n'ai jamais négligé de rechercher cette propagation. Bien que je n'en aie que trois exemples, j'espère que le fait vous paraîtra suffisamment démontré.

III. Avant de tirer des conclusions des observations qui précèdent, je tiens à citer les rares auteurs qui ont signalé l'altération des ganglions sus-claviculaires dans le cancer de l'estomac.

Voici comment s'exprime Hennoch à ce sujet (*Klinik der Unterleibs krankheiten*, 1863, p. 307) : « Le diagnostic de cancer de l'estomac est plus certain quand on peut trouver des ganglions durcis au-dessus de la clavicule... » A l'appui de cette remarque, Hennoch cite (p. 311) l'observation d'un malade qui mourut d'un cancer de l'estomac, et à l'autopsie, « immédiatement au-dessus de la clavicule gauche se trouvaient deux ganglions jugulaires, mous, ayant le volume d'un uf de pigeon et la consistance de la pierre. »

Dans une clinique publiée en 1875 (*Berliner klinische Wochenschrift*, t. 1), Friedreich insiste à propos du diagnostic du cancer de l'estomac sur la présence d'une tumeur ganglionnaire dans le creux sus-claviculaire. Chez le malade qui faisait le sujet de cette leçon, « la fosse sus-claviculaire gauche était remplie par un piquet de ganglions tuméfiés, durs, indolores, atteignant pour quelques-uns les dimensions d'une noisette. »

On trouve le passage suivant dans le traité de Leube (*Die Krankheiten des Magens und Darms*, in *Handbuch... von Ziemssen*, t. VII, 1876, p. 127) : « Un indice des plus certains de l'existence d'un cancer de l'estomac que la simple cachexie, c'est la tuméfaction des ganglions lymphatiques périphériques, avant tout de ceux de la région sus-claviculaire (Virchow). Toutefois, elle manque assez souvent et peut naturellement tenir à d'autres causes. »

Comme on le voit, Leube attribue à Virchow, et non à Hennoch, le mérite d'avoir mentionné cette altération des ganglions cervicaux dans le cancer de l'estomac. Je ne sais ce qu'il y a de fondé dans cette assertion ; j'ai vainement recherché cette mention dans le *Traité des tumeurs*.

IV. Les faits que je viens de vous communiquer me paraissent démontrer que le cancer de l'estomac peut, exceptionnellement il est vrai, se propager aux ganglions du creux sus-claviculaire. Il semble même résulter de ces faits que :

1° La propagation du cancer de l'estomac aux ganglions du creux sus-claviculaire est une preuve de généralisation du cancer, mais avec un point d'élection ; et ce qui me surprend, ce n'est point la distance qui sépare les ganglions de l'organe primitivement lésé, ce n'est pas l'absence d'altération des ganglions ou des organes intermédiaires, c'est l'absence d'altération des ganglions lymphatiques.

En terminant, je tiens à vous dire que la discussion sur les cancers latents et les pseudo-cancers est encore ouverte, j'ai pensé que vous écouteriez avec intérêt cette modeste contribution à l'étude du cancer de l'estomac.

FIG. 67.

[175]

SUPPLEMENT: A. J. S., n. s. Vol. VIII, No. 4, p. 949

gation. Although I have only three examples I hope that the fact will seem to you sufficiently established. . . .

iii. Before drawing conclusions from the preceeding case reports, I am anxious to mention the few authors who did call attention to the alteration of the supraclavicular glands in cancer of the stomach: Henoeh (*Klinik der Unterliebs-krankheiten*, 1863, page 307); Friedrich (*Berliner klinische Wochenschrift*, Number 1 for 1874);—Leube (*Die Krankheiten des Magens und Darms in Handbuch . . . von Ziemssen*, Vol. 7, 1876, page 127). Leube attributes to Virchow and not Henoeh the merit of having mentioned this alteration of cervical ganglion in cancer of the stomach. I do not know how much truth there is in this assertion; I have vainly sought mention of this in the Treatise on Tumors. . . .

iv. The facts that I have just communicated to you seem to me to prove that cancer of the stomach may, exceptionally it is true, be propagated to the glands of the supraclavicular cavity. It even seems to follow from my three case reports and from the two cases reported with some details, one by Henoeh, the other by Friedrich that this secondary alteration of the glands affects particularly the left side of the neck. That is a proof of the spread of cancer, but with a favorite point; the thing that surprises me is not the distance that separates the glands of the organ first attacked, is not the absences of alterations of the gland, or of the intermediate organs, but is this very unusual localization in the supraclavicular cavity.

In closing may I be permitted to state that diagnosis should take advantage of this anatomic fact. As the discussion on latent cancers and pseudo cancers is still open, I thought that you would hear with interest this modest contribution to the study of cancer of the stomach.

QUESTIONNAIRE

1. What are the chief causes of abdominal distention?
2. What fluids may invade or accumulate in the peritoneal cavity?
3. What is the derivation of the word ascites?
4. What is an exudate; a transudate?
5. What is Clark's sign; Toma's sign?
6. What is a watershed; a drainage basin; a catchment basin?
7. Name the four chief drainage basins in the peritoneal cavity.
8. What are the boundaries of these basins?
9. What is the supracolic division of the abdomen; what organs are contained in this region?
10. Divide the peritoneal cavity into ten drainage basins or fairly definite spaces in which pus or other fluids may accumulate. Give the boundaries of each space.
11. Illustrate the manner in which these various basins communicate with one another.
12. Explain how changes in position effect liquid accumulations within the peritoneal cavity.
13. What is the mesentery of the small intestine; what is its length; its direction?
14. Describe the attachment of the roof of the mesentery.
15. Upon which side of the peritoneal cavity are collections of pus and blood most frequently encountered? Explain.
16. Describe the transverse mesocolon; to what is it attached?
17. Into what divisions does it separate the peritoneal cavity?
18. What is the length of the transverse colon; its normal position in the abdomen; its relations to the stomach?
19. What is meant by Morison's space?

20. What is the subhepatic space?
21. What organ or organs may perforate into the subhepatic space?
22. Bound Morison's space.
23. What is the hepatorenal pouch?
24. Bound Petit's triangle.
25. Describe the methods for inserting a drain into the hepatorenal pouch.
26. What is the right infracolic space? Its boundaries?
27. What is the left infracolic space? Its boundaries?
28. Describe the pouch of Douglas.
29. What is the best manner in which to displace loops of small bowel in order to examine the right infracolic space; the left infracolic space?
30. What is the duodenojejunal angle; its location?
31. Describe several methods by which to drain the pelvis.
32. Describe methods for draining an appendectomy wound.
33. Describe drainage after cholecystectomy; repair of perforated peptic ulcer; after operation for acute pancreatitis.
34. Describe methods for securing dependent drainage for the pelvis; for Morison's space; the left infracolic space.
35. What is the space of Retzius?
36. What is meant by stab wound drainage?
37. What are the advantages and disadvantages of employing stab wounds for bringing drains to the body surface?
38. Define dropsy, hydrops, anasarca, edema, hygroma, exudation, effusion, fluid, ascites.
39. Name some of the basic laws regarding fluids which prove of special interest to the diagnostician.
40. What is Pascal's law; Archimedes' principle?
41. Describe the important findings upon inspection, palpation, percussion and mensuration, in an abdomen markedly distended with ascitic fluid.
42. What are the best tests for detecting small amounts of free fluid within the peritoneal cavity?
43. What is meant by ballottement?
44. What is meant by dipping with ascites? Describe the technic for eliciting this sign and state its significance.
45. What is meant by the fluid wave sign?
46. Give methods for detecting the fluid wave with ascites.
47. What is meant by shifting dullness?
48. Why does free fluid within the peritoneal cavity shift but slowly with postural changes?
49. What veins of the anterior abdominal wall become distended with obstruction to the portal vein?
50. What veins of the anterior abdominal wall become distended from obstruction to the inferior vena cava?
51. What is meant by the "caval veins?"
52. What is a reducible hydrocele; its significance?
53. How may abdominal distention due to ascites be differentiated from that due to fat? from that with accumulations of feces and gas?
54. Differentiate hydroperitoneum from ovarian cyst; distended bladder; hydronephrosis.
55. What is the appearance of the abdomen with marked gaseous distention of the large bowel; of the small intestine?

PYOGENIC AND NON-PYOGENIC KIDNEY INFECTION

FROM A PATHOLOGICAL STANDPOINT*

CHARLES Y. BIDGOOD, M.D., F.A.C.S.

HARTFORD, CONN.

IT IS not an uncommon experience in the practice of urology to encounter such a case as the following, which is presented in brief summary in order to illustrate one finding:

CASE I. C. R., admitted to the Hartford Hospital June 13, 1927, on the service of Dr. G. Gardiner Russell, temperature 100.8°F. Complaint: pain in the right side. Examination revealed an enlarged, tender right kidney. The voided urine contained a moderate amount of pus. Cystoscopic examination revealed a normal bladder. Ureter catheterization demonstrated no obstruction. Phenol-sulphonephthalein given intravenously showed appearance time, right kidney, three minutes; left kidney, three minutes; secretion, right side 9 per cent, left side 11 per cent, in thirty minutes. Urine obtained from each kidney was sterile to culture. A few days later a large perinephritic abscess was evacuated by Dr. A. M. Rowley. Culture of the pus showed *Staphylococcus aureus*.

The point to be demonstrated in this case is that sterile urine may be secreted by a kidney which is the site of a staphylococcus infection of sufficient intensity and duration to result in a perirenal abscess.

In contrast to this, is the common finding of chronic infections of the kidney and pelvis caused by organisms of the colontyphoid group without severe damage to the kidney or great harm to the patient, and it is the purpose of this report to

demonstrate the pathological condition which may ultimately result from an untreated colon infection of the kidney with continuous good drainage of the pelvis, in comparison with the end result seen in the above case, a coccus infection, in similar circumstances.

CASE II. Mrs. R. L., age forty-two, was admitted to the Manchester Memorial Hospital December 3, 1928, complaining of pain in the left back.

Present Illness. Onset six months before admission to the hospital. At that time the patient first noticed a dull, dragging pain in the left side, most noticeable at the end of an active day. This pain was located in the left back and side and radiated downward towards the groin and leg. It has never been acute and she has had no attacks simulating kidney colic. Four months before admission to the hospital she began having an occasional slight chill, followed by profuse sweating which would cease after a few hours. She thinks that she has been having a slight fever in the afternoon and evening during this time, because she has felt warm and her skin has been flushed. For the past three months it has been necessary for her to get up at night to void three or four times, and during the day she has voided about every hour and a half. There has been no dysuria, no hematuria, no urgency. During the past month her pain has become more constant and more severe. It has been located definitely over the left lumbar region, and the patient has noticed on palpating her side that a mass was present there.

* Read before the New York section of the American Urological Association, November 27, 1929.

Past History. Except for the present illness the patient has been a normal, healthy woman. A review of the eye, ear, nose and throat,

lous and there are numerous striae. On inspection, respiratory movements are found equal and normal on each side. On palpation no

FIG. 1.

cardiorespiratory, gastrointestinal and nervous systems is negative; also the urinary tract up until the present illness.

Personal History. The patient has had ten children, all normal labors. Nine are living and well, one died in infancy. No miscarriages. Menstrual history: periods have always been regular and normal, no bleeding between periods. Family history negative for tuberculosis, cancer, etc.

Physical Examination. The patient is a well developed, well nourished, adult female, forty-two years old, lying quietly in bed, apparently in no pain. Temperature 99°F., pulse 85, respiration 20, hemoglobin 95 per cent, red blood corpuscles, 4,400,000.

Examination of the eyes, ears, nose, mouth, throat normal; thorax and lungs normal; cardiovascular: heart not enlarged, apex beat is in the fifth interspace within the nipple line. Pulse 80, regular, good quality. Blood pressure 130/70. Extremities normal, reflexes normal.

Abdomen. The abdomen is slightly pendu-

FIG. 2.

epigastric tenderness is found, no masses. No tenderness, masses or muscle spasm felt in the right flank or costo-vertebral angle. No suprapubic tenderness, bladder not distended. In the left flank and costovertebral angle a large mass is felt. This is found to be well up underneath the ribs and to extend almost to the mid-line anteriorly and downward as far as the crest of the ileum. It is slightly irregular on palpation; it does not fluctuate; it descends on inspiration; it is moderately tender, and there is definite muscle spasm in the costovertebral angle. Catheterized urine shows a large amount of pus and a stain smear shows many Gram negative bacilli. The specific gravity is 1020; reaction acid, sugar and diacetic acid, negative.

Cystoscopy. The cystoscope enters readily and shows cloudy urine in the bladder. Bladder capacity 450 c.c. On inspection the entire bladder mucosa shows a diffuse catarrhal inflammation. No ulcers, tumors, stones seen. No diverticula. The trigone is slightly reddened and granular. Both ureteral orifices are normal in size and contour, but the left orifice is reddened and there is seen coming from it long shreds of inspissated pus. Clear urine is being secreted from the right side. No. 6 catheters ascend to each kidney without meeting any obstruction, and clear urine is obtained from the right side, and very purulent urine from the left. Intravenous phenolsulphon phthalein shows the appearance time on the right side five minutes; secretion 25 per cent, in thirty minutes. On the left side no phenolsulphon phthalein appeared in thirty minutes.

Microscopic examination of the urine obtained from each kidney shows the urine from the right kidney to be free from pus, and a stain smear showed no organisms. On the left side the urine contained a large amount of pus, and a stain smear showed many colon bacilli. Culture of the urine for twenty-four hours showed the right side to be sterile and the left side to contain many colon bacilli.

X-ray Report (Dr. D. J. Roberts, Roentgenologist):

The stereoscopic x-ray examination of the urinary tract before and after the injection of each kidney pelvis shows the right kidney outline to be somewhat enlarged, with normally filled pelvis, calices and ureters. The left kidney outline is not well defined. Throughout the region of the lower calices on the left side there are poorly defined semi-opacities suggesting debris or calcareous changes in the kidney substance. Following injection of this side the kidney shows a marked deformity and disintegration, the general appearance suggesting multiple abscess formations, the major and minor pelves appearing considerably contracted. The ureter, while it is slightly enlarged throughout its lower two-thirds, is otherwise negative in appearance.

Roentgen Conclusions. Marked disintegration of the left kidney cortex with contractures of the major and minor calices, and calcareous deposits in the kidney substance (the general appearance compatible with advanced tuberculous changes).

Final Diagnosis. Chronic colon bacillus infection of the left kidney, with a functionless kidney.

Operation. The patient was placed in the usual kidney position and an incision made beginning at the costovertebral angle and extending downward and anteriorly to a point opposite the anterior superior spine of the ileum. The external and internal oblique muscles and transversalis were divided and the perirenal fascia exposed. This was opened and the perirenal fat exposed. Digital examination failed to reveal any line of cleavage between the perirenal fat and kidney, the entire kidney having been completely destroyed and replaced by scar tissue. It was therefore necessary to remove the perirenal fat with the mass. This was done, all fibrous bands being doubly clamped, divided and ligated.

The tissues at the upper and lower pole were similarly treated until the entire mass, includ-

ing the perirenal fat, was free. The ureter was isolated below the mass, doubly clamped, divided and ligated. The pedicle was triply clamped, divided and doubly ligated. In so doing a small vessel of the pedicle was made to bleed slightly, but was quickly caught and ligated. Two rubber tissue drains were inserted into the depth of the wound and the muscle layers closed with a mattress suture of No. 2 chromic catgut. The skin was closed with fine silk.

The patient's condition at the end of operation was entirely satisfactory.

Following operation the patient had an uneventful convalescence and was discharged from the hospital three weeks later with the wound completely healed, and the urine free from infection.

Pathological Report of Specimen Removed (Dr. Ralph Kendall, Pathologist):

Macroscopic examination: The specimen consists of an oval fibro-fatty mass, weight 858 gm., measuring $15 \times 9 \times 8$ cm. At one side a tube-like structure is seen which has the appearance of a thickened ureter. On section the bulk of tissue shows ordinary fat lobules separated by increase in fibrous tissue. At the center of the mass there is more dense gray white fibrous tissue, not sharply outlined, but roughly kidney-shaped, and through which are seen small cavities filled with white purulent material. The ureter can be traced into one of these cystic areas before it reaches this space. However, it passed through a dense, rather fibro-fatty tissue.

Microscopic Examination: The renal parenchyma is completely destroyed and replaced by a dense and cellular fibrous tissue through which occasionally are seen a few distorted tubules or rare glomerulus. The latter shows a marked dilatation of the capsular space. Throughout the entire tissue there is a marked round and plasma-celled infiltration frequently arranged as lymphoid follicles. Beneath the epithelium of the pelvis there is a massive round-celled and polymorphonuclear cell reaction. There is no evidence of tuberculosis. At the outer margin, the capsule of the kidney cannot be identified from the marked fibrosis of the parenchyma. There is, however, a thick layer of fatty tissue at the surface.

DISCUSSION

When any parenchymatous organ is invaded by bacteria, the resulting patho-

logical process is determined by a combination of circumstances: the dosage and virulence of the organism, the degree of immunity of the host, and the efficiency of drainage. The first two of these are considerations in any infection; but the last, drainage, is of particular importance, because by it, more than any other local factor, is the ultimate life or death of the organ determined.

When one speaks of drainage in kidney infections, the usual conception conveyed is drainage of the kidney pelvis. But it is believed by several investigators, such as Dyke, that drainage within the kidney parenchyma, particularly at the inception of the infection, is the basis upon which rests the correct explanation of the fact that different types of organisms, notably those of the colon typhoid group, and the pyogenic cocci, often yield dissimilar pathological processes.

To be more explicit, there is an opinion among investigators that organisms belong to the colon typhoid group show a predilection for that portion of the kidney which has its origin in the Metanephros, namely the ureter, pelvis and collecting tubules, that portion of the secretory mechanism which is efferent to the glomerulus; while the cocci, according to the experiments of Dyke, are disposed to lodge as emboli in the vessels afferent to the glomerulus. If this theory be acceptable, it would follow that in the latter location there would be no opportunity for drainage into the renal pelvis, the glomerulus serving as a barrier, and for lack of this drainage, abscesses would result, located chiefly in the cortex and boundary zone of the kidney. This, we know, is the clinical picture frequently seen in staphylococcus infections. It is conceivable that such lesions might heal spontaneously; but it is more often true that once inaugurated, the infection will progress, ultimately terminating in a kidney studded with multiple confluent abscesses. If the lesion is confined to only a part of the kidney, to a localized area of miliary abscesses, the

so-called "carbuncle of the kidney" results. If the abscesses rupture into the pelvis of the kidney and there is interference with pelvic drainage, pyonephrosis will result, and if the rupture occurs through the cortex, a perinephritic abscess.

With infections due to the bacteria of the colon-typhoid group, the pathological picture is different from that described here. This group of organisms never results in multiple disseminated abscesses of the kidney parenchyma, perinephritic abscess, or "carbuncle of the kidney," because, being efferent to the glomerulus, drainage is allowed.

The likelihood that the above hypothesis may be true has considerable support clinically. With regard to coccus infections, it is the not common experience of all urologists to encounter suppurative lesions of the kidney with multiple parenchymatous and perinephritic abscesses, usually staphylococcus in origin, with sterile urine being secreted by the infected kidney. This would indicate that the site of the infection is such that it cannot drain into the kidney pelvis, and since it is reasonable to assume that if the infection were efferent at the glomerulus, at least some drainage would occur, it follows that the infection must be afferent to it, and that the glomerulus forms a barrier to drainage. Experimentally, the recent work of MacKenzie and Hawthorne shows that intravenous injections of colloidal particles in sufficient dosage, causes blocking of the capillaries of the glomeruli, and the intertubular capillaries which, if permanent, ultimately causes infarct formation.

In contradistinction to this is the common experience that in the majority of simple, acute and chronic infections of the kidney due to organisms of the colon-typhoid group, recovery is the rule without serious renal damage, if there is efficient pelvic drainage, probably because the infection attacks primarily that portion of the kidney efferent to the glomerulus.

This difference is also supported by statistics. Cabot and Crabtree's analysis

of a series of kidney infections reveal focal suppurative lesions to be the rule in 27 cases of coccus infections, with cortical abscess in 20 of them. In their studies of lesions produced by the colon-typhoid group, they found no cases presenting the same condition when pelvic drainage was good, and their studies of sections stained for bacteria showed the presence of bacilli in the collecting tubules to be the rule. In their conclusion they say: "we believe that lesions produced by cocci and pyogenic bacilli differ essentially from the lesions produced by the non-suppurative organisms, chiefly the colon-typhoid group."

CONCLUSIONS

The theory presented here is not original in this paper, but is based largely upon the

experimental work of Dyke, and is used as a working basis for the explanation of clinical differences often seen in coccus and bacillary infections of the kidney.

The case demonstrated represents an instance of autonephrectomy caused by an untreated colon bacillus infection. It is presented because we believe that it typifies the final pathological picture which may result if such infections are allowed to progress without therapeutic interference.

[For discussion see p. 964.]

SURGERY OF THE FIBROUS PROSTATE

AN OPERATION FOR TOTAL EXCISION OF THE GLAND*

E. GRANVILLE CRABTREE, M.D., F.A.C.S.

BOSTON, MASS.

THE trend in urological surgery seems to me to be definitely away from uniformity in operative measures to be applied to obstructing lesions of the prostate gland. Many surgeons aim to approach the prostate by that operative procedure best adapted to the type of gland encountered. There seems to be an increasing number of surgeons employing both the suprapubic and the perineal approaches for prostatectomy. Early advocates of the suprapubic operation often held themselves purists, and did not ever depart from their conviction as to the superiority of the suprapubic route. Cancers, fibrous contractures, and large adenomata received similar treatment at their hands. Perineal operators lived up to their ideals with equal fervor and dragged large benign intravesical prostates through the perineum. Perusal of the literature on prostatic surgery of an earlier day indicates combative exposition of one method of approach to the exclusion of the other. In spite of this combative attitude both operations have survived on their merits. The fact remains that the great majority of obstructive prostates are operable with low morbidity and mortality by either method of approach.

A few years ago, on reviewing the end-results of operations for fibrous prostates in my own cases and those of other surgeons which happened to pass through my hands, I found a higher morbidity than average in patients suffering from fibrous glands. The type of lesions encountered were roughened prostatic cavities, tight internal sphincters, urethras contracted through the prostatic bed, an occasional non-catheterizable patient, and others with continued symptoms in spite of operation, and persistent infection. A

few of these patients had been operated on more than once in the hope of improving the end-result. The group of patients represented the combined efforts of eight surgeons. It was easy to see that the fibrous prostate offered by no means so good a prognosis as benign hypertrophy. It was with the hope of producing better results that I began to do total prostatectomy on this type of case. It is my purpose to submit in this communication the end-results of a group of 15 cases operated upon in this manner. It was my intention to do an occasional case by this method until sufficient time had elapsed to determine the value of the surgical measure before adopting it as routine.

In discussing total excision of the fibrous prostate, I do wish to discredit in any way the cautery operations devised by Caulk, Collings and others for prostatic bars. The work of these pioneers in this type of work is most praiseworthy. I believe such electrocautery procedure should be encouraged in every case to which the operation is applicable. However, since in many fibrous prostates a bar does not constitute the whole of the obstruction, but a shrunk atrophic gland is itself capable of offering resistance to voiding; since intraurethral impingement of small nodules of hypertrophy from lateral lobes often exist together with bar formation; since fibrosis may exist without bar formation; and dilatation of the atrophic fibrosed gland is an unsatisfactory means of maintaining free drainage in an old man who wants cure of his condition, a group of cases suitable for a more radical treatment than the cautery is constituted. It is with this group that I have concerned myself in performing total removal of the prostate gland.

* Read before the American Urological Association (N. Y. Branch), November 27, 1929.

I had for some time been employing total prostatectomy by the perineal route in suitable cases of carcinoma of the

formed a certain number of suprapubic dissections of fibrous glands. I do not believe these have been nearly so satis-

factory as those operated on by the method of total prostatectomy which I shall later describe in detail. In transvesical dissections I found that I was not obtaining as smooth a cavity and was apt to find portions of prostate left near the membranous urethra, that is, the tip of the prostate and at the bladder neck. These irregularities gave obstruction, perhaps not greatly noticeable immediately

FIG. 4. Midline incision in posterior neck of bladder so that when sutured to urethra, floor of bladder is on line with urethra and there is no sagging of trigone.

after the operation but occasioning considerable trouble some months later. In addition I have found that suprapubic operations for the fibrous glands are, in my hands, not nearly so easy technically as the operation through the perineum. I

therefore abandoned the suprapubic approach in favor of the perineal operation.

In preliminary preparation of these

diverticulum a suprapubic drain was placed, and the patient allowed to continue on that drainage until the perineal

FIG. 5. Perineal incision used for prostatectomy.

patients drainage was accomplished by the urethra in some, by suprapubic cystotomy in others, and in a third group by combined urethral and suprapubic drainage. In making the choice of drainage to which the patient was subjected, the urethral type was used in those patients in whom a short period of drainage preparation was all that was required. The majority of the patients preferably had suprapubic drainage by cystotomy. It is my impression that by suprapubic drainage prostatic congestion is diminished, the patient bleeds less at operation, and on the whole the bladder is in better condition at the time of the subsequent operation on the prostate. Where calculi are present suprapubic drainage is of course preferable to urethral drainage. In still a third group of cases, particularly those in which diverticulum was encountered as a complication to the fibrous prostate obstruction, combined urethral and suprapubic drainage was employed. Greater ease in handling the bladder pathology through a primary wound was the basis for decision in favor of urethral drainage previous to the operation for diverticulum. At the time of operation for

FIG. 6. Tractor opened out and prostate drawn down. Prostate, en masse, being dissected free from surrounding tissue by handle of knife.

operation was completed. In a few cases urethral drainage was not well tolerated and suprapubic drainage was established immediately.

Bilateral vasoligation was done in all cases as a preliminary to prostatic operation. While vasoligation is not a 100 per cent guarantee against testicle complications in prostatic obstruction, it so diminishes the morbidity from this disease that it is well worth while. I have been unable to detect any systemic change in the patient as the result of this procedure. Except by reference to the patient's history, I do not believe I can distinguish between those patients in whom vasoligation has been done and those in whom it was not a part of the prostatic operation. The time at which vasoligation is done is at the institution of drainage in those cases in which urethral drainage is employed, and at the time of suprapubic

cystotomy in those instances where suprapubic drainage is used. In those patients in whom the period of urethral drainage was short, ligation of the vas was sometimes done at the time of the prostatic operation. In others where diverticulum complicated the operation for prostatic obstruction ligation of the vas was done at the time of the operation for diverticulum. Vasoligation has proved to be a boon to the prostatic patient and a source of great comfort to the surgeon, and I have no doubt, has saved the lives of a few cases that were narrowly balanced and in which a severe degree of epididymitis has seemed to be the deciding factor which finally caused the loss of the patient's life.

DESCRIPTION OF THE OPERATION EMPLOYED

With the patient in the lithotomy position, an inverted U perineal incision was made and carried down to expose the central tendon of the perineum. The tendon was severed and the prostate exposed freely by reflecting the posterior layer of the membrane of Denonvilliers. Transverse section of the membranous urethra at the tip of the prostate was then made on a sound in the urethra, and Young's perineal retractor inserted into the bladder. At this point complete section of the membranous urethra can be made. By means of blunt dissection and sharp dissection wherever necessary the gland is readily exposed upon the bladder wall. By slightly increasing the traction on the perineal tractor the prostatic urethra can be opened at the internal orifice on the retractor as a guide. A smooth internal orifice can be provided with curved operating scissors by dissecting away the prostate from the bladder wall. Tenaculum forceps are then inserted into the internal prostatic orifice and the gland turned outward after the perineal tractor has been removed. By gentle traction and blunt dissection the gland can be sufficiently elevated to allow separation of the ejaculatory ducts with curved scissors.

All bleeding points can be snapped and tied at this point to insure a dry wound. Inasmuch as the fibrous gland is a small

FIG. 7. Space opened on each side of central tendon by fingers.

gland, the distance separating the bladder neck from the severed urethra is never great, and sufficient slack is obtained by traction on the bladder to easily approximate the bladder neck and the severed urethra. A large urethral catheter, as large as the urethra will permit, is then passed into the bladder and the bladder neck sutured to the urethra over this catheter. This forms a complete mucous membrane connection between the severed urethra and the bladder. If care is taken, sufficient prostatic urethra can be left to allow of the resuturing being done without greatly altering the position of the internal vesicle sphincter. A small perineal drain, usually of rubber dam or Miller wicking, or a light gauze pack can be placed, and the wound closed without further drainage. It has been my experience that with an open wound and the opportunity to ligate all bleeding points a rubber dam drain is

used much more effectively than the gauze pack. Bleeding has in no case been excessive and seldom has there been

supplementary incisions will be best seen by reference to the illustration. As will be noted by reference to the tables on end-

FIG. 8. Anastomosis of neck of bladder with stump of membranous urethra with interrupted chromic catgut.

FIG. 9. Prostate removed, showing opening at neck of bladder and cut end of membranous urethra.

more than a slight discharge of serous fluid. Rarely is there any leakage of urine through the perineum. Where the bladder base is not flattened by removal of the prostate, two procedures have been employed to accomplish this aim. The first of these is as follows:

A v-shaped excision is made in the posterior lip of the bladder orifice in such a way as to lower the posterior margin of the bladder orifice to the level of the bladder floor. (See Fig. 4A.) As near an approximation as is possible is then made so that the severed urethra may close this opening. Such enlargement of the bladder neck is usually too great for the urethra to close it entirely. These patients may leak some urine through the perineum in the course of convalescence. In the other procedure, two lateral incisions are made to produce a lip on the posterior surface of the internal orifice, which lip is sutured to the severed end of the urethra. (See Fig. 4B.) The nature of these two

results in these cases, there is no evidence that such enlargement of the internal sphincter increases the tendency to incontinence or decreases the function of the bladder. I am convinced that flattening of the bladder base is an important procedure particularly in those cases of contracture in which the internal orifice of the bladder is greatly elevated above the position of the ureters in the bladder. As has been already mentioned this is not always a necessary procedure for most often, removal of the prostate sufficiently flattens the bladder base to make such an incision unnecessary. As one might expect in those cases in which gauze packing of perineal wounds, or insertion of bags for hemastatic control is not indicated, the patient's convalescence is extremely comfortable, drainage and sutures are removed within a few days, and the perineal incision heals by first intention. Where suprapubic drainage has been employed it is usually removed at the time of operation, but the

suprapubic tube can be left indefinitely. I have made no provision for retaining the urethral catheter other than the usual adhesive tape fixtures applied to the penis for this purpose. Since bleeding from the prostatic cavity is not apt to enter the bladder because of the suture line which excludes it, drainage from the bladder is usually clear from the beginning and gives no trouble whatever. I do not know the fate of the vesicles where the ejaculatory ducts have been severed, but it is reasonable to suppose that with ligation of the vas atrophy takes place. At any rate, neither in the course of convalescence nor subsequently have we encountered any difficulty whatever with the vesicles which have been excluded from their normal urethral drainage.

I wish it to be clearly understood that I claim nothing original about the type of operation performed in this small group of cases. As you will see by reference to the drawings, Young's operation for total excision of the prostate for carcinoma has been adapted to the fibrous gland, to which adaptation this operation is particularly well fitted. I wish you to look upon this group of cases as an experimental

group and to remember that I have but slowly developed it in order to give sufficient time to determine the final end-results as to function in these cases before doing a larger series. I feared that the scar tissue formation about the prostatic cavity might be sufficient to cause contraction of the prostatic urethra to a degree in excess of that which usually takes place following any type of prostatic removal. It is only since I have satisfied myself that such contraction had not taken place, following my review of those cases, that I have been willing to adopt the operation, but have not included the latter cases in the list given in Table 1. The end-results of the two operations seem to be equally satisfactory.

Postoperative return to function averages for the group of 15 cases, fourteen days, with 7 cases in the neighborhood of ten days. It was rare that urine leaked through the perineal incision at all, and equally rare that blood complicated drainage in any degree whatever following operation. The comfort of the patient was distinctly noteworthy. There was no operative mortality. One patient, satisfactorily convalescent, returned to the

hospital after a period of stay-at-home and died of pneumonia. His chief handicap at the time of operation was emphysema of the lung. There was but one case in which the functional result was not entirely satisfactory. That patient showed some dripping for a period of four months, but has since entirely recovered. In one other case a two-ounce residual persists. The urine has entirely cleared from pus and bacteria. This was noted at the end of a year and six months following the operation. The patient entered the hospital in uremia having had a long-standing over-distention with a very thick bladder wall showing extensive fibrosis. After a preliminary preparation of fifty-seven days, the perineal operation was done. I do not believe the type of operation influenced the persistence of residual, but rather that it represents the condition of the bladder.

DISCUSSION OF PAPERS BY DRs. BIDGOOD AND CRABTREE

DR. BENJAMIN S. BARRINGER: Dr. Bidgood's paper was of great interest to me, but I am confident that I will have to read it over carefully to see why cocci attack the cortex and colon bacilli the pelvis of the kidney. I confess that I do not understand this, though I know that both Dr. Crabtree and Dr. Bidgood consider this to be the case. I should like to hear Dr. Bidgood's explanation.

The results shown by Dr. Crabtree's operation are most extraordinary. I fear (even though I may be alone in such a statement) that if I took 15 of my best prostatectomy cases and measured the residual after operation, I would find at least one-half of them with one dram to one-half ounce. Possibly it might not exist, and perhaps the amount is exaggerated; but I am quite sure that probably 13 out of the 15 would show residual. His extraordinary results in this direction was the first thing which struck me in considering his operation. If he can get such good function in a condition which has puzzled all of us for a good many years, I think we should adopt this operation ourselves.

DR. BARRINGER: I cannot precisely follow Dr. Crabtree's technic, because fibrous prostates do not dissect out bluntly in my hands, probably because they are done suprapubically and I do not know how to do this

There has been no occasion for any reoperative measures of any kind whatever. The urethras are uniformly smooth, admit a sound or cystoscope freely, and show a functioning internal urethral sphincter. I believe this type of operation has a definite place in prostatic surgery for a selected group of cases lying between those where satisfactory relief can be obtained by cautery or punch operation, and the typical prostate, a benign hypertrophy, which is treated either by the suprapubic or the perineal route by enucleation. It affords satisfactory end-results in a group of patients in which they have been least satisfactory. In addition it appears from the results as tabulated in this group of cases, the oldest of which is five years since operation, to prove that the operation affords a permanent and adequate relief of symptoms.

perineal operation. I want more than anything I have heard of lately to see him perform the operation, and see what I can make out of a heretofore puzzling condition.

I am a poor one to discuss this subject, because for years I have advocated no operation for various conditions of the sort, such as carcinoma of the prostate, conditions of the trigone and of the bladder neck, etc. The less operating, the better, has been my opinion, having in mind the patient's condition rather than the operation itself. That is nothing against what Dr. Crabtree has said, however.

At any rate, I think it is time I saw Dr. Crabtree do his operation, as his results are even more extraordinary than would at first appear when we consider how bending-over-backwards he is in the matter of accuracy in recording end-results, checking up statistics, and the like.

DR. THOMAS J. KIRWIN: Dr. Crabtree's paper has, it seems to me, defined with acuteness a problem over which controversy has been waged for a generation. I have listened to discussions of this character by urologists whose leadership in the profession is a matter of common consent. It has occurred to me that after all has been said the controversy represents no real differences of principles. Nobody denies that irrespective of method or

technic, the chief objective of any prostatectomy is preservation of the sphincters without injury to the rectum or the ejaculatory ducts. Fundamentally, then, the question is whether that objective may be more successfully reached suprapubically or perineally. As you all realize, of course, the situation is perplexed by practical considerations in individual cases. Dr. Keyes only last week made us the beneficiaries of his long experience when he read before the Academy of Medicine his illuminating paper upon the "Prospects of the Prostatic." In the discussion which followed emphasis was again put upon the practical aspects of the problem. There was apparently an agreement that the operator should employ the method in which he was most proficient. The practical force of this suggestion has a strong appeal, but I feel it has a tendency to react as an obstacle to progress. However, I take it that even the most partisan of suprapubists will hardly fail to be convinced by Dr. Crabtree's reasons for preferring the perineal method. Cases of small fibrous prostates, as he has made plain to us, present difficulties all their own.

In a résumé of recent statistics of perineal versus suprapubic prostatectomies, I find the following:

Young: 1049 Prostatectomies by "conservative perineal" procedure, with 36 deaths in hospital (3.4 per cent). 108 Suprapubic prostatectomies, in 55 of which final results are known 76 per cent were stage procedures—final results good in 60 per cent.

Davis, Edwin: 91 Perineal operations under sacral anesthesia with 1 death (1.1 per cent). Average age of patients, seventy years, with 9 men over 80.

Hinman: Personal cases (number not known). Mortality was between 2 and 3 per cent. In 95 per cent of the surviving cases the cure was complete. There were no persistent rectourethral fistulae and no incontinence of urine as a result of the operation.

Lowsley: Suprapubic cystotomy, 8.4 per cent; perineal, 5.7 per cent. It is only fair to state that these figures include all the staff and residents.

Keyes: 76 Entered hospital, and 11 died there, a total mortality of 14 per cent. Among the 76 patients 10 were not operated upon at all, 3 died promptly without operation, 7 others were temporarily relieved without operation, 4 died after preliminary suprapubic

drainage, and another having been drained refused prostatectomy.

Dr. Bidgood's paper was not only a scientific contribution, but a constructive one. I believe that the gist of his paper was, as he stated (after the work of Dyke of London, England), that the typhoid group and the cocci group of bacteria enter through afferent vessels and have a predilection for the cortex of the kidney, causing carbuncles and perinephritic abscesses. But to me the most important point was the fact that typhoid bacilli and the colon group not only enter by way of the afferent vessels, but pass out through the efferent route into the collecting tubules, causing huge pyonephroses. This type usually results in complete loss of function and nephrectomy. I remember that Dr. Lowsley cystoscoped a patient on whom a diagnosis of perinephritic abscess has been made (in which Dr. Keyes concurred) in spite of the fact that the urine was clear. Bacteriological examination of both specimens showed them to be clear and sterile, but a perinephritic abscess was nevertheless suspected, which was found upon operation to be due to a coccus infection.

DR. JOHN H. MORRISSEY: I would like to know just what Dr. Crabtree means by fibrosis of the prostate. These cases come to us as purely urinary conditions presenting a symptomatology similar to that of the prostatic in general, i.e., dysuria, retention and symptoms of infection. I should like to know on what he makes a diagnosis of fibrosis: digital, cystoscopic or radiographic evidence.

Excluding a ball valve adenoma, which is especially definite, it seems to me that these cases can be classified as anything you want to call them: median bar, contracture of the vesical neck, etc. In the absence of these particular conditions, then, we come to the point where we are dealing with a chronic infection. We are probably all familiar with the recent work of Von Lackum, of the Mayo Clinic, who reported a large number of cases all of which responded adequately to treatment directed towards infection of the prostate, following a punch operation. Bumpus originally reported a punch series showing striking results, with relief of obstruction, etc. Von Lackum later found the results not entirely satisfactory in these cases, but obtained even complete relief by eliminating the infection. Of course in a consideration

of any cases from the Mayo Clinic one must always remember the departmental limitations of that institution. Anyone doing surgery will naturally favor his own particular procedure, and Von Lackum's reports naturally reflect his own department, where he is restricted to massage, the use of dilators and sounds, etc. I believe, however, that in the absence of any pathology in these prostatic cases, as noted previously, they may be considered as merely chronic infection and treatment should be so directed. Not every patient will let you cut into the urethra and attack the prostate through a perineal incision, unless he can be convinced that he has a definite surgical condition. It is therefore necessary for the most part to direct treatment towards elimination of the infection. If this cannot be done, then perhaps a perineal operation is indicated.

Unless one is familiar with the technic of the perineal operation, he cannot appreciate how minor this may be as far as the patient is concerned. The mortality is relatively nil, and the discomfort quite minor.

In any large series of seminal vesiculectomy operations that I have done in the past I felt the results were due not so much to removal of the vesicles as a liberal incision and drainage of the prostate. I have seen prostates fully the size of an English walnut come down to that of a small almond following some 8 or 9 linear incisions. Although Dr. Crabtree has removed the whole gland in these fibrous prostate conditions, as he calls them, I think his results are due principally to relief of the infection. Whether this could have been accomplished just as well by draining the area, removing a small adenoma if present and avoiding the sacrifice of the pieces of gland left, is the question. I do feel and know that complete removal of the gland is a radical procedure; and in many cases of complete removal and suture of the vesical neck to the severed ends of the urethra, urinary control is hard to get. Undoubtedly in all these perineal operations a good part of the control is due to a resulting scar. Possibly in chronic infection we do have a scar which maintains control. Surely if we excise an entire prostate we run a serious risk of getting dribbling and lack of control as a result. I would be very much interested to know what the sections from the glands removed showed: whether chronic infection, whether the remaining glandular tissue was entirely obliterated

by the fibrosis, or whether or not there were any indications of carcinoma cells in the slides.

My point of view towards these kidney cases is not so much a consideration of what the causal factor may be, but what to do with them. In the first case Dr. Bidgood showed here, my view would be that we were dealing with a healed tuberculosis of the kidney with secondary colon infection, and that the kidney should be removed. I must say that my interest would be limited to that consideration alone in such a case.

DR. NATHANIEL P. RATHBUN: We are all familiar, of course, with the theory of the bacterially infected pelvis draining into the urinary tract, and that cocci have a habit of attacking the cortex, cortical infections very many times giving clear urine in the presence of a serious infection of the kidney. However, I did not quite gather from his paper why this occurs.

I think Dr. Crabtree has made an important and original contribution. Dr. Crabtree has had the courage to do a radical operation for a condition which has puzzled all of us. My results in using chiefly the suprapubic approach have never been entirely satisfactory. Several cases where on a second occasion we have opened the bladder widely, with full exposure, and excised portions of a bar with the knife or endotherm, have proved fairly satisfactory, although not to the degree that Dr. Crabtree mentions.

Dr. Crabtree has called his group of cases a small one, but to me it would be large considering the fact that there was no residual. I have had no results approaching his. It occurs to me that it behooves those not familiar with the perineal route to perfect themselves in that technic, and make more frequent use of this operation. The danger, however, lies in the possibility of many cases of incontinence if this original operation of Dr. Crabtree is employed indiscriminately, as it requires a high degree of technical skill.

I confess that I have not had much success with the Young punch or the method advocated by Dr. Collings. I have had some cases where the obstructing bar was removed with the Stern knife. I get better results from the suprapubic approach.

DR. A. R. STEVENS: I think we have all realized for a long time, as has Dr. Bidgood, that the common pyogenic organisms were the ones usually encountered in perinephric

infections, and that it is exceedingly uncommon to meet any member of the colon group. I should want to read his paper over to thoroughly understand his explanation of just why cocci attack the cortex of the kidney and colon bacilli the pelvis. I hope that Dr. Crabtree will discuss Dr. Bidgood's paper, as I think it was prior to the War that he and Dr. Cabot came down here and read a paper on the subject.

At that time Dr. Cabot had a great deal to say about the "long wheel base" of the colon organisms, and in some way amusingly explained it on that basis. I think perhaps that might help to fix the idea in our minds. However, staphylococci are not only found in perinephric infections. It is not a very unusual experience to meet staphylococci with pus in catheterized specimens of urine. To me they have been very difficult cases. I have had three or four very distinct, clean-cut cases of staphylococcus infection (obtained in pure culture) confined to the pelvis and immediately adjacent portions as far as I could make out, on which I tried various dilatations and irrigations without accomplishing anything. One case was freed from the infection by giving intravenous neosalvarsan. In all cases I tried capricol, the drug supposed to be prescribed in such cases; but without benefit.

The very nice way in which Dr. Crabtree has worked out his whole group is to be commended. It seems to me, however, that cases diagnosed as fibrous prostate: i.e., trigonal, vesical neck or median bar conditions, should first of all be treated by some simpler therapy, some form of punch or cautery. Dr. Crabtree thinks he can pick the individuals cases which cannot be helped in that way and will require his more extensive prostatectomy, and I would be glad to know just how that conclusion is arrived at. It seems to me that of the cases which are generally regarded as fit subjects for the various punch operations, three groups have proved unsuccessful: (1), where there is a spinal cord lesion which has not been recognized; (2) the group occasionally met in which there are definite hypertrophied intraurethral lobes (and all cases of this kind should be examined as carefully intraurethrally as intravesically to exclude hypertrophied lobes); and (3), the group which I suppose prompted this more radical operation: that without intraurethral lobe and without spinal cord lesion. In these cases we at Bellevue have employed the punch

operation frequently, with suprapubic control, and have found that after removing four or five obstructing pieces and in some cases going a step beyond and with a scalpel cutting through any remaining scar so that a perfectly pliable posterior aspect to the vesical outlet was left, certain individuals have not become well. A few such cases have been operated upon four times. I had supposed these were individuals who had a very marked predilection for the formation of scar tissue with infection, and of course all these cases have infection after they are opened up. However, they may represent prostates with scar formation extending very deep into the gland. On the basis of either explanation, such individuals would be ideal subjects for Dr. Crabtree's operation.

DR. CLYDE W. COLLINGS: I think Dr. Stevens hit the nail on the head when, in discussing Dr. Crabtree's paper, he mentioned the question of diagnosis. The reason transurethral operations fail is that the patient has intraurethral lateral lobes as well as a fibrous bar, or (as found recently in a Bellevue patient) an enlargement of the subtrigonal type. In this instance we remove two benign lobes underneath the trigone, the size of a small English walnut, after the patient had been punched per urethra or suprapubically four times. Then again, some patients may have a fibrous bar plus a median lobe. We will be asked by the patient or his doctor to do a transurethral operation. These operations usually fail.

It seems to me that if we stick to our knitting and follow only the absolute indications for the transurethral operation, we will be delighted instead of disappointed with the results. I have always stressed the point that this method of cutting through the prostatic urethra with the high frequency current should only be used where there is a definite fibrous bar with a cystoscopic picture of the bas fond, and elevation of the neck of the bladder, as the instrument is withdrawn into the posterior urethra. Sometimes we see a fibrous scar obstructing the neck of the bladder after prostatectomy. This is entirely relieved by the cutting current. And thirdly, patients with obstructing bar due to carcinoma of the prostate, can usually be relieved of their residual urine and put off the time when they will probably come to a suprapubic tube.

DR. MAXIMILLIAN STERN: I agree with Dr. Collings in saying that Dr. Stevens hit the nail

on the head with regard to small fibrotic prostates. However, I cannot agree entirely with Dr. Collings as to resection and diathermy methods.

This gives me an opportunity to tell Dr. Lowsley that his "I told you so" was absolutely correct. At a time when I was very enthusiastic over the resectoscope he said that I would live to say that he was right in contending that it was applicable to only a limited number of cases. The temporary results obtained in frankly infected cases were, I think, entirely due to the fact that we got drainage for a time. All of these prostates undergo the atrophic process of normal senile degeneration until (probably due to the incidence of infection) they get so bad that surgery is the only recourse. However, many people agree with me that operative methods are not the only way of handling a prostate until infection gets out of hand. Up to a certain time it is only proper to try to deal with these prostates as organs normal in all other respects. Very good results are obtained by dilatation, massage, hydrotherapy and diathermy, and in a growing number of cases prostatectomy is averted.

In connection with infective processes and vasligation, I would mention an idea which recently occurred to me. I had an old gentleman as a patient, on whom a vasligation had been done with the idea of causing prostatic atrophy. The prostate and seminal vesicles were infected; the two lateral incisions over the vasa broke down and remained open. These persisted as points of drainage from the vesicles. This case suggested the plausibility of cutting across the vas and letting the distal end drop into the scrotal sac, and of sewing the proximal end to the open wound to permit of drainage. This I have never done but it seems more logical than simple ligation.

In any case, I cannot say that I approve of vasligation in general, and in infected cases I am especially opposed to it.

In frankly fibrotic prostates such as Dr. Crabtree describes I still believe that resection, together with other therapeutic measures, will yield results superior to major surgical procedure.

DR. GEORGE W. STARK (SYRACUSE, N. Y.): I have only two observations to make on these very interesting papers. One is that in Syracuse, as in other smaller cities, we get out cases earlier because of our closer contact with the internist, resulting in a better chance of curing them without surgical interference. The other is

that the Bostonians have been trying for years to put over the theory that certain infections attack certain parts of the urinary tract, because of its embryological development; but I do not think that this theory will work out any better than the rest.

Personally, I do not think all perinephric abscesses arise from the kidney, but that they can come from the outside and approach that organ. Two weeks ago a woman came to me who on examination was found to have a mass in the upper right quadrant. There was nothing pathological in the kidney, the function was normal, and I was so positive that there was no connection with the kidney that I advised an anterior incision. A large inflammatory mass was found attached to the capsule of the kidney. The capsule was free. I believe that had this case been allowed to go on longer, she would have had a perinephric abscess. In such instances, of course, the theory of infection suggested by Dr. Bidgood would not work out.

I have made cultures of several hundred cases of kidney infections, and while the preponderance showed colon bacilli, quite frequently staphylococcus aureus, and once or twice a streptococcus was found.

DR. C. Y. BIDGOOD (*Closing*): I realized before presenting my paper this evening that it was more or less theoretical and had no apparent practical application, as has been pointed out in the discussion.

Assuming that the idea is correct that the colon bacillus tends to attack that part afferent to the glomeruli, Dr. Barringer and Dr. Rathbun have both asked why. I confess that I do not know, unless it can be explained on the basis of bacterial selectivity.

Dr. Morrissey mentioned the possibility of tuberculosis on the basis of the pyelogram shown, as of course anyone would. The case was considered from that viewpoint, too, until numerous microscopic sections from all parts were made and no evidence of tuberculosis was found.

Dr. Stevens' report of a case cured by intravenous neosalvarsan was interesting, because I supposed that when a small abscess due to a coccus infection ruptured into the afferent tubules there would immediately be drainage into the pelvis which would result in a positive culture in the urine. According to Dr. Stevens, he did not get much result from pelvic lavage, probably because lavage would not reach the ultimate source high up in the parenchyma. Cocci often respond to intravenous neosalvar-

san, presumably because it reaches that portion of the kidney afferent to the glomerulus.

Dr. Stark has made some interesting remarks about perinephric abscess. We all know that originally they were classified as primary and secondary, i.e., primary where one could find no abscess in the kidney to account for the perinephric abscess, and secondary where such an abscess was found. That nomenclature has been altered, and those cases in which we find no abscesses in the kidney itself designated as paranephric. Those to which Dr. Stark has called attention are the paranephric type, a slightly different condition from that considered here.

DR. E. G. CRABTREE (*Closing*): The reception accorded the new idea I have presented (or perhaps I had better say "adaptation of an old idea") has been very gratifying.

The question raised by Dr. Barringer regarding my good results as far as residual is concerned leads me to ask him to define normal limits of bladder emptying; that is, how often the normal bladder really empties itself. I have recently considered residual urines in our work on pregnant women at the Boston Lying-In Hospital, only to find wide variation in function in the same patient. If I get complete emptying on most occasions, I take that as a determination of residual. If one took the top figure rather than the lower point in determining residual, quite a marked difference in the degree of function would be shown.

I agree with Dr. Stevens in his statement as to the difficulty experienced in deciding by cystoscopic means alone what kind of prostate we are dealing with. The one-eyed vision offered is not sufficient. I trust that the future will add something more definite to our ability to diagnose these cases. At my clinic we are cystoscoping all of our prostatic cases, and doing cystograms and urethrograms in addition. By comparing these findings and the picture noted at operation with the specimen obtained, we feel that we have learned a little, and may in the future become more expert.

Some confusion seems to exist as to what type of prostate I am operating by the method described. A fibrous prostate is defined as the kind which when felt by rectum is small, not nodular but elastic, and does not raise the question of malignancy. Cystogram shows no deformity of the bladder. Urethrogram shows a short prostatic urethra. In such cases we do total prostatectomy, providing a smooth, regular prostatic urethra through which urine passes

as readily as in the postoperative benign hypertrophy. I do not wish you to infer in any way that the paper presented here tonight is antagonistic to the work of Dr. Collings and others in handling the prostatic bar. These patients belong to a different group. Dr. Collings had made it clear that he *cuts prostatic bars*, but varies from that procedure when there is some other form of obstruction. The group I spoke of is intermediate between Dr. Collings' cases and the ordinary type of prostate in which some surgeons (as Dr. Rathbun has mentioned) do a suprapubic dissection. The method which I have followed for these cases has proved a satisfactory way for me to meet the problem.

Dr. Stevens and others have mentioned prostatic treatment by massage. We are not talking about the same group of cases. I recognize that there is a hard prostate typical of chronic infection and also one which is atrophic and fibrous but obstructive.

Total prostatectomy for carcinoma and that for a fibrous gland are operations of very different magnitude, the former very often technically difficult, the latter much easier. Its virtue in these cases lies in better functional results and more certainty in obtaining satisfactory end results.

Let me say a word in regard to the "long wheel base" of the colon bacillus. I agree with Dr. Bidgood that this is only a theoretical consideration, and I realize that we are on disputed ground. Dr. Cabot and I contended that even though a coccus pyelitis may occasionally be found, the characteristic lesion of the coccus was abscess formation, that of the colon bacillus, tubular inflammation. The work Dr. Cabot and I did some years ago reported data based on pathological examination of tissues taken from the kidney and perinephric region at operations in which an abscess had been found. The group of specimens were examined and sections stained for bacteria instead of relying on cultures where overgrowth of other organisms by the colon bacillus might occur. True perinephric abscess rarely showed any other organism than the coccus. I believe there were but two cases in which bacilli alone were found, and these were not colon bacilli. I still think, after ten years, that if we rely on cultures less and on sections stained for bacteria more, perinephric abscess will be found a coccus disease, and the renal reaction to the "long wheel base" colon bacillus that of a distinctly different disease.

INTRAVENOUS INJECTION OF GLUCOSE

ITS EFFECT ON THE RESPIRATORY QUOTIENT*

HARRY KOSTER, M.D., F.A.C.S., W. S. COLLENS, M.D. AND M. A. GOLDZIEHER, M.D.

BROOKLYN, N. Y.

FROM clinical reports the armamentarium of the surgeon has been augmented by a very important factor in the intravenous administration of glucose. During the past five or six years reports from all over the world speak favorably of such intravenous administrations in the treatment of all types of post-operative complications, ranging from slight nausea and vomiting, attributed to anesthesia, to the dehydrating and debilitating effects of such very serious complications as peritonitis and intestinal obstruction. Wherever acidemic states are even remotely suspected its use is advocated very urgently. All types of toxemias have been cited as indications for its employment and almost uniformly the results have been reported to be favorable. In all instances these reports are the results of clinical observations. In no instance that we know of have the results been checked up in a scientific manner, nor is there any explanation based on a scientific foundation of the means by which it accomplishes improvement. A consideration of these facts led us to the problem which is as follows:

1. What happens to glucose after it is injected intravenously?
2. What influence does it have upon the postoperative state?

There are two possible ways in which glucose may be of value to the body. One which immediately suggests itself is its value as a fuel. The other method by which it may be of value is as a foreign body irritant which when introduced into the blood may stimulate the defense mechanism. We shall concern ourselves solely at this time with the consideration of the value of glucose as a fuel in the body.

The history of metabolism is definitely associated with the recognition of the value

of the respiratory quotient as a method for the determination of the relative utilization of the various food stuffs, fats, carbohydrates and protein. Normally in the postabsorptive state after a fourteen to eighteen hour fast the respiratory quotient ordinarily is between 0.78 and 0.82. When proteins alone are burnt the respiratory quotient is about 0.82 and when fats alone are burnt the respiratory quotient is about 0.7. When a glucose plethora is produced in the blood either by the ingestion or intravenous injection of sugar, the respiratory quotient rises toward unity. During the postabsorptive state a rise in the respiratory quotient after the administration of glucose is to be expected normally. Woodyatt¹ has demonstrated that in the normal animal or in man, assimilation of glucose can go on to the extent of 0.8 to 0.9 gm. per kilogram body weight per hour. In order to be certain that we produced a carbohydrate plethora in our experiment, we used these figures and gave 50 gm. of glucose intravenously per 60 kg. of body weight.

METHOD

This consisted of the determination of the respiratory quotient after a fourteen to eighteen hour fast, the administration of 50 gm. of glucose intravenously (250 c.c. of a 20 per cent solution) followed by another respiratory quotient one half hour later. Blood-sugar determinations before and after the glucose administration were also made. This represents the control experiment. The same procedure was then carried out at the time of operation, the glucose being administered during operation and the respiratory quotient determined immediately after the operation within one half hour after the administra-

Submitted for publication, March 11, 1930.

tion of glucose. Spinal anesthesia which does not affect the quotient, was used in all cases. Unselected cases in which various

from which energy metabolism can be calculated and the relative part that each food stuff plays in its production.

FIG. 1. Degree of rise in respiratory quotient following intravenous glucose administration.

types of abdominal operations including hernias were performed. The procedure used in the control experiment was subsequently repeated at intervals over a period of sixteen days. Cases with postoperative febrile states were not included because it was felt that the respiratory quotient obtained under such conditions might be misleading. In a few instances in which there was postoperative fever the respiratory quotient was also determined and the results will be cited separately.

All determinations were made with the Bailey modification of the Tissot calorimeter and the Henderson modification of the Haldane gas apparatus. Blood sugars were determined by the Folin Wu method. Precautions were taken to obtain the proper mental and physical relaxation before the respiratory quotient estimations were made. All determinations were performed by the same individual.

APPARATUS AND METHOD

The Bailey calorimeter is used to determine the respiratory exchange of the body

The subject inspires outside air. One-way valves automatically partition the inspired from the expired air. The expired air is collected in a balanced spirometer for a period of approximately ten minutes. The CO_2 and O_2 content of this air is then determined by gas analysis.

The O_2 and CO_2 of outside air being known, the difference between these and the CO_2 and O_2 of the expired air represent the O_2 consumed and CO_2 excreted in the internal respiration of the body. From this data, the energy metabolism of the body is obtained.

A face mask was used in all the determinations. The mask was tested for leaks regularly, and supported by a large rubber dam binder to seal the edges.

The valves for partitioning the air are made of soft gum rubber and completely collapse when the current is reversed.

The spirometer has a capacity of 100 liters. The bell is counterbalanced in any position by a chain and counterweight. Only expired air is collected in the spirometer. The volume of gas collected during

a determination is brought to standard conditions by correcting for temperature and pressure. The air sample for analysis is collected with a Bailey sampling bottle.

The Henderson Haldane gas analyzer was used in our work. The accuracy of the determinations were maintained by checking the analysis of the sample on two different machines. Although at the outset of our experiments we employed the usual alkaline pyrogallate solution for absorbing the O_2 , our subsequent determinations were performed with oxysorbent. We found it much superior to pyrogallate solutions from the standpoint of speed and accuracy in taking up all the O_2 in the sample.

RESULTS

The results of studies in 14 cases are charted in Table 1. These are typical of the 30 cases studied. Eight preoperative controls are presented which uniformly indicate a decided rise in the respiratory quotient following intravenous glucose administration. In 4 of the cases charted, immediately postoperatively there is a decided diminution in the rise of the quotient following the glucose injection. The 2 cases which show 0.04 and 0.05 rise respectively were complicated in that the quotients were determined at a time when there was no longer any anesthesia, and when the patients were beginning to experience severe pain to which they responded by marked physical and mental activity. From the first to the sixth day there was no rise in the quotient excepting in Case IV, in which there was a rise from 0.69 to 0.76. These figures, however, are still within the range of quotients obtained when fat alone is oxidized. From the seventh day on there is a definite tendency toward elevation of the quotient after glucose administration. The longer the interval of time between the operation and the determination, the closer the approach of the quotient, after glucose administration, to the normal. In starvation, when the liver has been depleted of its glycogen, the administration of glucose

fails to elicit a rise in quotient because of its immediate conversion into glycogen and storage. During acidemic states the true nature of the quotient may be obscured by the pathological elimination of CO_2 . In the cases studied both these sources of error were eliminated. The patients were not starved, and the absence of acidosis was shown by determinations of the CO_2 combining power of the blood.

DISCUSSION

It can be seen from these studies that there is no rise in the respiratory quotient following intravenously injected glucose for approximately one week after operation. The slight variations observed are within the limits of experimental error. This period coincides with the clinically critical postoperative period. The failure to obtain a rise in the quotient occurs at a time when the physical restlessness and mental anxiety would under ordinary conditions in themselves produce a rise. Thus the inability to produce a rise in the respiratory quotient following glucose administration is particularly significant. Similar results have been observed in experimental animals. Collens and Murlin² in unpublished results were unable to produce a rise in the quotient following intravenous glucose in animals with their hepatic arteries ligated. Cori and Cori³ observed no rise in the quotient following glucose in eviscerated rats.

The glucose injected cannot be accounted for by the respiratory quotient. Apparently then the postoperative state is definitely associated with an inability to utilize glucose. The fate of this glucose is now under investigation and will subsequently be reported.

Two cases reported show the effect of insulin during the postoperative state. In both cases there is a uniform and decided rise in the quotient following its injection. This suggests the possibility that insulin stimulates the oxidation of glucose during the postoperative state.

It is also suggested by these studies that

* Respiratory quotient following intravenous administration of 17 units of insulin.

the inability to utilize sugar runs parallel to the severity and the duration of postoperative shock. The patient in CASE VII who was subjected to a very extensive operative procedure and who had a left internal saphenous vein phlebitis from the eleventh postoperative day on, is illustrative. The patient in CASE XIII who was operated on for a gangrenous cholecystitis had a prolonged and troublesome convalescence. These two were the only cases in the series who ran stormy postoperative courses and at the same time were the only patients who sixteen and thirteen days respectively after operation showed no rise in the quotient following glucose injection.

It appears from these results that the administration of glucose early in the postoperative state is of questionable value as a fuel. Following operations a large percentage of patients suffer to a greater or less degree from vomiting. These patients who cannot retain, digest and absorb foods, burn their own reserve of carbohydrates and fat and have a tendency to develop an acidemia which in turn

favors further vomiting. Intravenous glucose has been strongly advocated as the panacea in these cases; but according to our results, there is no evidence to indicate that the exogenous glucose at this stage can spare fat and protein breakdown.

CONCLUSIONS

1. The respiratory quotient does not rise following intravenous glucose administration after abdominal operations for a period of approximately one week.
2. Insulin may be able to stimulate the oxidation of sugar during this period.
3. The postoperative state is definitely associated with a disturbance in carbohydrate metabolism.

NOTE: We desire to express our thanks to the members of the Staff of the Crown Heights Hospital whose cooperation made it possible to secure the clinical material for study.

MANAGEMENT OF THE THYROID HEART*

JOHN C. RUDDOCK, M.D., F.A.C.P., AND C. G. TOLAND, M.D., F.A.C.S.

LOS ANGELES, CALIF.

THE "thyroid heart" as commonly known is that heart condition or abnormality which is found in patients who present themselves for the treatment of a thyroid dysfunction.

This paper is prompted because of controversies between surgeons in respect to the use of digitalis in the preparation of thyroid cases for surgery. Should digitalis be used in all cases? If not, in what type of case is digitalis indicated? Or should digitalis not be used? In this discussion the merits of the different types of treatment (medical, surgical or radiological) for goiter will not be considered.

Every surgeon handling goiter cases should associate himself with an internist or cardiologist and should have a careful study of the cardiac condition made before surgery is attempted. In no other condition will a close cooperation between the internist and the surgeon so strikingly improve the service to the patient as in the surgical treatment of a thyroid dysfunction.

The thyroid heart is a disordered action of the heart as seen in cases of thyroid disease. It is most frequent in cases of exophthalmic goiter (Graves' disease) and the so-called toxic adenoma. Although we may find occurring simultaneously with goiters any or all of the conditions which may occur in heart disease, still there is nothing that can be found macroscopically or microscopically that is pathognomonic of thyroid disorder. It is a functional disturbance, and should be considered as a disordered action of the heart dependent and secondary to a disease of the thyroid gland which *cannot be cured* unless the causative agent is eliminated, namely the *thyroid disorder*.

PATHOGENESIS OF THE THYROID HEART

The disordered action of the heart is dependent upon a disordered function

of the thyroid gland, except in those cases in which an enlargement of the gland or its position mechanically, through pressure, etc., alters the functions of neighboring structures and is the cause of cardiac disturbances (goiter heart of Rose).

There is an increase in size of the thyroid gland with an increased vascularity and a corresponding hypersecretion of the gland. Plummer believes that so-called toxic adenomata produce a pure hyperthyroidism and that the excessive secretion differs in no way from the normal secretion; but in exophthalmic types the secretion is not only excessive, but is qualitatively changed from the normal. According to Kendall this change is brought about by an alteration of the imino group (CO-NH) and not a change in the iodine content. Regardless of what the chemical change is or the type of goiter with which we are dealing, there is a profound effect upon the nervous system. These patients as a rule are nervous and emotional. They speak and move quickly. Tremors of the hands and tongue are common and we have a symptom complex that is identical with an overstimulation of the sympathetic nervous system (sympatheticotonia).

The activities of the internal organs are by no means so dependent upon nervous control as are the activities of the voluntary muscles. If the nerve supply to the latter is interrupted their activities cease. If it is interrupted in the former, no serious results necessarily follow. Nervous impulses modify and direct the activities of the internal organs but are not essential to a continuation of these activities. The central vegetative nervous system has a depressor action whereas the sympathetic system has an accelerator action. There is a definite something secreted or controlled by the thyroid gland which controls the balance between these two

*Read before the Pacific Coast Surgical Association, February 22, 1929.

systems. This is easily seen when a direct comparison is made between the clinical manifestations in a case of hyperfunctioning thyroid gland and a case in which there has been a total removal of the gland (Table 1).

TABLE 1

| Total Removal of Thyroid (Cachexia Thyreopriva) | Hyperfunction of Thyroid (Graves' Disease) |
|--|--|
| 1. Absence of gland | Swelling of the thyroid gland; hypervascularization of gland. |
| 2. Cold skin, without flushings. | Vasomotor instability. |
| 3. Slow small, regular pulse. | Frequent, tense and at times irregular pulse. |
| 4. Uninterested quiet stare without expression of life. | Anxious, changing glances. |
| 5. Narrow palpebral aperture. | Wide palpebral aperture (exophthalmos). |
| 6. Slow digestion and excretion, poor appetite, requiring little food. | Abundant secretions, excessive appetite with increased need of food. |
| 7. Retarded metabolism. | Increased metabolism. |
| 8. Skin thick, opaque, dry and scaling. | Skin thin, transparent and moist. |
| 9. Short, thick fingers with broad ends. | Long slender fingers with pointed ends. |

| 11. Slow sensation, apperception and action. | Increased sensation, apperception and action. |
| 12. Lack of thoughts, interest and emotion. | Flight of ideas, psychic excitation. |
| 13. Slow, awkward muscular movements. | Constant activity and haste. |
| 14. Stiffness of the extremities. | Tremor and increased mobility of joints. |
| 15. Constant chilliness. | Unbearable feeling of heat. |
| 16. Slow difficult breathing. | Superficial breathing with imperfect inspiratory expansion. |
| 17. Increase of weight. | Loss of weight. |

INFLUENCE OF GOITER ON THE HEART

Because of the accelerator effect of the sympathetic nervous system in goiter there is a speeding-up of the cardiac rate (heart hurry) or tachycardia. Tachycardia may be either simple or paroxysmal in type and is often spoken of as palpitation. The minute cardiac output of blood from the heart is increased in direct proportion to the rapidity of the heart beat and it naturally follows that the centripetal circulation, or the rate of flow through the capillaries, is likewise speeded up,

resulting in an increased oxidation of the tissues. The general level of blood pressure may be normal, elevated or reduced; but the pulse pressure is almost regularly increased. These changes in pulse rate and pulse pressure roughly parallel the changes in metabolic rate and they doubtlessly depend in part upon the general level of body metabolism. The accidental murmurs heard over the heart, the palpitation and excessive arterial pulsations are all due in part to excessive cardiac activity.

THE SYMPATHETIC NEUROSIS ACCOMPANYING THYROID DISEASE

Palpitation, tachycardia, dyspnea and general muscular weakness are all common and constant symptoms of thyroid disease. These symptoms should not be interpreted as heart signs. Palpitation is a symptom of disturbed sensation. It is a mark of the heightened nervous irritability so characteristic of thyrotoxicosis. Tachycardia or increased rate is merely a physiological adaptation and, like dyspnea, a physiologic response, and partly due to the general muscular weakness and inefficiency of the thyrotoxic organism in doing work.

DECOMPENSATION

Because of the excessive cardiac activity a thyroid heart will eventually become decompensated. The length of time that the heart must carry this added load is in direct proportion to the degree of decompensation. Long-standing cases frequently show evidence of myocardial disease, such as cardiac dilatation and hypertrophy with incidental extrasystoles or auricular fibrillation. Myocardial failure is more frequently noted in the chronic nodular goiter that brings the patients to the doctor after the age of forty than in the acute exophthalmic type.

A decompensated thyroid heart presents the same problem as any other decompensated heart. The signs of decompensation are the same rapid irregular rhythm (fibrillation), enlargement of the liver,

edema of the extremities and general anasarca (ascites and pleural effusions).

Auricular fibrillation is not alone a sign of cardiac decompensation. A heart may fibrillate and still be compensated. This peculiar irregularity is, in most instances, constant, so much so that it has been called the permanent irregularity (*P. irregularis perpetuus*). As a rule patients who have an auricular fibrillation from mitral stenosis or some other organic heart lesion are oblivious to the irregularity of the fibrillation, but the thyrotoxic patients, because of the heightened nervous irritability, are particularly distressed by the irregular beats and complain quite bitterly of them.

Auricular fibrillation in patients with thyroid disease is more amenable to treatment because it is not usually associated with any organic heart lesion, and when present without any accompanying cardiac decompensation often disappears completely with the elimination of the offending cause, thyroid disease.

PREOPERATIVE TREATMENT

Having decided that the case of a patient with thyroid disease is a surgical one, our problem is to give such treatment as will take the patient through the surgical experience with the least risk. Our preoperative treatment is divided into two classifications:

1. Those cases with compensated heart.
2. Those cases with decompensated heart.

There is no difference in these two types of cases with the exception that digitalis is indicated in those cases with decompensated heart and not in the others. Both types of patients are placed in the hospital and given absolute rest in bed. The patient is not allowed up for any reason. Visitors are excluded and quiet is maintained as much as possible. The patient must be kept happy. The diet consists of nutritious meat-free foods, without tea or coffee, averaging 1500 calories per

day. Sedatives that do not contain alcohol are given as necessary for alleviation of excessive nervousness.

Both types of cases receive Lugol's solution of an average dosage of 15 to 20 minims three times a day in water after meals.

This treatment as outlined is used for both classes of patients for a period of one week to ten days prior to surgery. However, those cases with signs of cardiac decompensation are rapidly digitalized.

TABLE II
PREOPERATIVE TREATMENT

| Compensation | Decompensation |
|--------------------------------------|-------------------------|
| Rest in bed | Rest in bed |
| Sedatives | Sedatives |
| Lugol's solution | Lugol's solution |
| No digitalis | Complete digitalization |
| Quinidine Sulphate for Fibrillation. | |

DIGITALIS

It makes little difference in what form digitalis is administered; providing the preparation is potent and in a sufficient amount, digitalis effects may be confidently expected. It should be remembered that the tincture rapidly loses potency. The glucosides are soon reduced to inert sugars by exposure to light and air, so that the tincture should be freshly prepared if its potency is to be depended upon. The part of wisdom is to use few preparations and to obtain them from the same source. The powdered dried leaves are perhaps the preparation of choice.

Only rarely is there a true need of introducing digitalis otherwise than by mouth as it has been shown that where given in sufficient dosage a therapeutic effect may be observed in five or six hours and the maximum in twelve or eighteen hours.

Pardee found that the average individual disposes of about 22 minims of the tincture per day or the equivalent to 2.2 grains of the powdered leaf. Keeping this in mind the danger of the cumulative action of digitalis has certainly been overemphasized. Cushny has aptly compared the administration of digitalis in massive dosage to a

simple chemical titration in the laboratory. Where the strength of the reagent is known, it is safe to run in from the burette a relatively large quantity of salt, and then complete the reaction with a few drops as the end point is reached. If we obtain the desired result the dosage is adequate and further use of the drug is contraindicated.

Digitalis will not control a tachycardia and has been frequently maligned because it failed to do so. Lugol's solution is by far the better therapy. If however, the patient has evidence of cardiac failure, digitalis should be employed in exactly the same fashion as a preoperative measure as it would be in the treatment of cardiac failure without an operation looming upon the horizon.

There appears to be no justification for the routine employment of digitalis in patients with normal hearts before operation.

The Eggleston method of dosage and administration of digitalis has become standard and we can do no better than adhere closely to the rules as originally laid down by him. A rough easy modification of Eggleston's method is 0.2 grain or 0.01 gram of the powdered leaf per pound of body weight of the patient, and for the tincture ten times the same dose in cubic centimeters. This gives the theoretical total amount which a heart requires for complete digitalization within safe limits.

METHOD OF ADMINISTRATION OF CALCULATED AMOUNTS

1. When a patient has received no digitalis within ten days:

| | | |
|--------------------|---|---|
| Six hours apart | { | 1st dose: $\frac{1}{3}$ — $\frac{1}{2}$ of total amount |
| | | 2nd dose: $\frac{1}{5}$ — $\frac{1}{4}$ of total amount |
| | | 3rd dose: $\frac{1}{8}$ — $\frac{1}{6}$ of total amount |

Then $\frac{1}{10}$ total amount three times daily until digitalization is complete.

2. If patient has been receiving digitalis in preceding ten days the total calculated dosage should be reduced, the amount of

digitalis retained allowing an average of 2.2 grains excreted per day. If this cannot be done then the total dosage is reduced to 75 per cent and the procedure already given is followed.

TIME TO OPERATE

When all signs of decompensation have disappeared, usually seven to ten days after complete digitalization, surgical treatment should be instituted. To wait at this time will again subject the heart to those influences that caused the original decompensation i.e. thyroid dysfunction.

Quinidine sulphate is often invaluable in controlling the fibrillation in these cases where no decompensation is present or after the heart has become compensated.

SUMMARY

1. Surgeons should be associated with a cardiologist in the preoperative treatment of thyroid heart conditions.

2. The "thyroid heart" is a functional disturbance and cannot be cured unless the causative agent, thyroid disease, is eliminated.

3. Thyroid hearts eventually become decompensated.

4. Palpitation, tachycardia, dyspnea and general muscular weakness are not heart signs but are only evidences of the sympathetic neurosis accompanying thyroid disease.

5. A decompensated thyroid heart presents the same problem as any other decompensated heart.

6. Digitalis is of value only in the presence of a decompensation and is not used otherwise.

7. Digitalization should be quick and complete.

8. Digitalis is invaluable in lessening the cardiac output prior to operation and may be the deciding factor in the patient's recovery.

9. Operation must not be delayed after compensation has been restored.

SPLENECTOMY FOR THROMBOCYTOPENIC PURPURA HEMORRHAGICA

WITH CASE REPORTS*

HENRY F. GRAHAM, M.D., F.A.C.S.

BROOKLYN, N. Y.

THROMBOCYTOPENIC purpura hemorrhagica is characterized by:

1. A marked decrease in the blood platelets.

2. Normal coagulation time.
3. Prolonged bleeding time.
4. Absence of retraction of the blood clot.

5. Changes in the capillaries, and possibly the whole reticuloendothelial system.

The red and white cells are normal in character.

This disease is not hereditary, but it occurs most often in youth, from three and one-half years up. The bleeding may occur anywhere in the body, beneath the skin or mucous membranes, or from the vagina, rectum, or other orifices. The tendency to bleed is often well shown in these patients by the tourniquet test. Sufficient pressure in the blood pressure cuff to obliterate the venous flow but not the arterial, causes petechial hemorrhages.

The blood platelets originate from the megacaryocytes of the bone marrow and furnish a substance called thromboplastin which hastens coagulation.

There are various theories as to the cause of the disease:

1. That it is primary in the bone marrow and due to defective formation of platelets. If this is correct, why is there such a large and sudden increase in the platelets after splenectomy?

2. That the normal platelets are destroyed by a toxin in the blood.

3. That normal platelets are destroyed in the spleen.

The consensus of opinion of those who have studied the disease seems to be that the platelets are probably formed in normal numbers but are destroyed by the

spleen and the reticuloendothelial system. The capillaries also are altered so as to become more permeable, probably by a toxin.

Splenectomy has effected a cure in a considerable percentage of cases. It was first performed in 1916 by Kaznelson.

Whipple collected 81 cases. Of these, 73 were chronic. There were 6 deaths. Eight were acute with 1 death. Later reports from 61 showed that there were 51 good results, 4 fair results, and only 6 poor results; i.e. about 90 per cent were successful.

The fact remains that a few cases are not cured and splenectomy causes practically no rise in the platelets in some cases.

Morrison, Lederer and Fradkin report a case where an accessory spleen was seen but not removed at operation and a cure was not obtained. This may explain other failures.

Accessory spleens are commonly seen in the autopsy room and should be searched for at operation upon these cases of thrombocytopenic purpura. In the case about to be reported such an accessory spleen was found and removed.

The cases where an enlarged spleen is removed seem to do better than others.

Kaznelson early noted that, of 4 cases observed, 3 had an enlarged spleen.

In considering the advisability of splenectomy and the operative risk to be incurred, one must not forget that the disease itself at times proves fatal.

Hamilton and Waugh report a case that died with symptoms of intracranial hemorrhage within three months of the first hospital admission. The previous duration of the disease was not stated. Another fatal case is appended.

* Read before the Brooklyn Surgical Society, January 2, 1930.

Splenectomy, in normal individuals free from purpura, is followed usually by a marked increase in the platelets.

Most writers agree on the danger of splenectomy in the acute form and the unsatisfactory after-results in many cases, although Killins has reported an acute case with operation upon the sixth day and complete recovery.

The following case is one of thrombocytopenic purpura cured by splenectomy:

CASE I. K. S. Hospital No. 128190. First surgical service, Methodist Episcopal Hospital.

Age, sixteen Female. Born in U. S. Student Family physician, Dr. H. L. Hall.

Admitted to hospital August 4, 1928. Discharged August 23, 1928.

should have ceased, it continued unabated and contained large dark clots. The patient became increasingly weak and had four fainting spells, the last of which was upon the morning of admission.

The patient has always developed black and blue marks from even slight trauma from childhood up, and her hands and arms show such spots at the present time. Ergot has been taken by mouth for a few days and seemed to lessen the flow about one quarter.

Physical Examination: This shows a rather stout girl in an extremely weak condition and with great pallor of her lips and mucous membranes. Blood is coming from the vagina, and there are hemorrhagic spots on her hands and arms.

For vaginal examination, see record of curettage.

| Tourniquet test | | | Slightly positive | | | |

Past History: She has generally had good health but has had measles and pertussis and had trachoma eleven years ago. Her thyroid gland was somewhat enlarged at fifteen years. Her menstrual periods started at twelve years, have come every twenty-eight days, and lasted four days. The flow has been moderate. There have been no clots and no pain in the past.

Family History: Father and mother are living and well. There was no history of bleeding in other members of the family.

Present Illness: This started twelve days ago with bleeding from the uterus. This blood was bright red in color and about normal in amount for the regular period which was then due. After four or five days, when the flow

An admission blood count showed 2,400,000 red cells, 25 per cent hemoglobin, 6,400 leucocytes, 88 per cent polynuclears, and 32 per cent lymphocytes. The coagulation time was three and one-half minutes. The patient was Type III for transfusion.

A transfusion of 1,000 c.c. was given on the day of admission by the direct Unger method, by Dr. H. W. Mayes. Following this, the blood count rose to 3,136,000 red cells and 48 per cent hemoglobin. The bleeding from the uterus continued, however, and two days later, August 6, 1928, Dr. Mayes performed a dilatation and curettage. The uterus was found enlarged to the size of a two-months' pregnancy, but the curettage failed to yield any gross material, and microscopical examination showed

nothing but blood clot. The uterus was packed.

For two days following this operation, there was practically no bleeding, but, as soon as the packing was removed, the flow commenced again.

A blood count on August 9, 1928, did not show a great drop, but the platelet count at this time showed only 30,000 platelets. This was repeated the following day and gave 40,000 platelets. A smear at this time showed slight pallor of the erythrocytes and moderate anisocytosis and slight poikilocytosis with an occasional rare normoblast, i.e., 2 normoblasts to every 100 W.B.C. counted.

The blood pressure was 112/70. The bleeding time was over sixteen minutes. The tourniquet test was slightly positive.

A consultation was held with Dr. N. Rosenthal, hematologist of Mt. Sinai Hospital. He confirmed the diagnosis of chronic purpura hemorrhagica and stated that the blood picture was typical of thrombocytopenic purpura hemorrhagica. He advised splenectomy if transfusions failed to arrest the menorrhagia.

On August 11, 1928, another transfusion of 600 c.c. was given. Following this the bleeding gradually ceased, and the patient returned home.

On April 13, 1929, the patient again returned to the hospital. Four months previous to admission, she had a profuse period of longer duration than usual. The two succeeding periods were also increasingly long and profuse, and she had been suffering from uterine bleeding for a month preceding her admission. Her pulse was 120 and blood pressure 105/50.

A transfusion of 540 c.c. was given on April 14, 1929, and following this, the right arm bled for three hours. The bleeding was finally stopped by thromboplastin. The blood count was 2,050,000 red cells, 20 per cent hemoglobin, 8,400 leucocytes, and 79 per cent polynuclears with 21 per cent mononuclears; later there was an occasional nucleated red cell.

The platelet count on April 16, 1929 was 136,000. A second transfusion on April 17, of 760 c.c. brought the blood count up to 3,040,000 red cells and 27 per cent hemoglobin. The platelets dropped to 119,000. Even after these two transfusions, the bleeding time was over seventeen minutes, although the coagulation time was only three and one half minutes.

Dr. Rosenthal, at another consultation, advised a splenectomy.

On April 22, 1929 a transfusion of 900 c.c. was given by Dr. Seymour Clark who left the vein exposed at the close of the transfusion.

A splenectomy was then performed (Henry F. Graham) through an upper left rectus, hockey-stick incision. The spleen measured $15 \times 11 \times 4\frac{1}{2}$ cm. It was soft and composed of glandular tissue throughout. Microscopical sections showed a marked proliferation of the reticuloendothelial cells. There were large areas where these cells had completely replaced the lymphoid tissue. There was a short main pedicle and a larger accessory pedicle deeply placed at the upper pole. A small accessory spleen was found in the neighborhood. This was also removed.

At the close of this operation, Dr. Clark introduced 700 c.c. of blood from another donor directly into the same vein. The patient

* Dr. Rosenthal.

left the table in good condition. The following day the red cells were 3,270,000, hemoglobin 28 per cent platelets 136,000.

The highest postoperative temperature was 102°F. A gastric lavage was done on the day following operation because of vomiting, but only clear fluid was obtained.

The bleeding from the vagina continued following operation, but on the third day became less, and on the fourth day there was no vaginal bleeding. It had ceased and did not recur while the patient was in the hospital. There was primary union in the operative wound.

On April 26, the platelet count was 310,000, coagulation time three and one half minutes, bleeding time two and one half minutes. On April 29, it was 298,000, and the red cells were 3,450,000 with a hemoglobin of 35 per cent. May 4, the platelets were 306,000, red cells 3,580,000, hemoglobin 38 per cent. May 17, platelets were 332,000, hemoglobin 47 per cent.

Patient discharged as recovered on May 19, 1929.

On August 5, her weight was 209, red cells 4,208,000, hemoglobin 75 per cent, leucocytes 11,900, polynuclears 78 per cent, small lymphocytes 11 per cent, large lymphocytes 9 per cent, transitionals 2 per cent, coagulation time two minutes, bleeding time one and one half minutes, platelets 536,000.

This patient has been seen several times since her discharge from the hospital. The last time was Sept. 4, 1929. She has remained well. Her periods are now normal.

A second case of thrombocytopenic purpura was found in our hospital files.

CASE II. No. 116999. Female, eighteen years. Admitted, February 10, 1927. She was bleeding from the gums, lips, nose and vagina, and this had persisted off and on for eight months since the birth of a child. The vaginal bleeding had lasted a month, and there were petechiae under the skin and an enlarged spleen. The hemoglobin was 17 per cent, and the red cells were 1,450,000. The coagulation time was four and one half minutes. The platelets, on two counts, were 60,000 and 28,000. The bleeding time was not taken. She bled from the rectum and stomach and died February 24, 1927 in spite of a transfusion.

Differential diagnosis should exclude hemorrhagic purpura not of the thrombocytopenic type.

An interesting case illustrating this was seen at the Norwegian Hospital:

CASE III. M. S. No. 25109. Thirty-five years. Admitted May 6, 1927.

An operation was performed consisting of an appendectomy, cholecystectomy, trachelorrhaphy, and perineorrhaphy. On May 19, nine days later, she began to bleed from the perineum, and this was resutured without result. Further history revealed that her father was a bleeder and that she once bled profusely after labor.

The blood came steadily in a slow stream from her vagina until she became pulseless and unconscious. A telephone consultation with Doctor Ottenberg gave us a tentative diagnosis of purpura hemorrhagica and the advice that massive transfusion was indicated. Two donors were used in succession and 1480 c.c. of blood given, with recovery. Two later transfusions, amounting to 1730 c.c., brought the total used in four days to 3210 c.c. The platelet count was 1:8 on May 23 and 1:10 on May 26, totaling 266,000. The lowest red cell count was 2,710,000 with 40 per cent hemoglobin, polynuclears 84 per cent, lymphocytes 16 per cent, white cell total 11,600.

An interesting case illustrating one of the problems in differential diagnosis is the following one of aleucemic leucemia.

CASE IV. No. 121922 December 4, 1927.

The patient was a female aged forty-nine, showing multiple ecchymoses of the skin and mucous membranes. The red cell count was 3,800,000, hemoglobin 70 per cent. The platelets varied between 30,000 to 105,000 on the day following transfusion. The white cells were 4,000, the polynuclears 22 per cent, the lymphocytes 78 per cent, coagulation time six and one half minutes, bleeding time five minutes.

Discharged December 18, 1927 as improved.

The diagnosis was made by Dr. N. Rosenthal. A low total white count and a high differential lymphocyte count, with many immature forms, characterizes this condition.

Hemophilia gives a family history, being transmitted through the female with active bleeding in the male. The coagulation time is much prolonged. The bleeding time is often diminished. The platelet count is normal.

[NOTE: For bibliography see author's reprints.]

AMEBIC ABSCESS OF THE LIVER*

METHOD OF TREATMENT

INJECTION OF CAVITY WITH IODIZED OIL FOR DEFINITE LOCALIZATION

CLIFFORD LEE WILMOTH, M.D., F.A.C.S.

BALTIMORE, MD.

ABSCESS of the liver is one of the most serious complications or sequelae of *endameba histolitica* infection of the intestinal tract. Although involvement is seen much more frequently in tropical countries, the condition is by no means uncommon in temperate countries.

The chances of recovery in amebic abscess of the liver depend to some extent upon the stage of the disease when first diagnosed, the site and size of the abscess, and whether multiple or single. Of more importance, however, is the method of treatment to be followed, as demonstrated in recent statistics which show that the mortality has dropped from a tremendous height to below 5 per cent.

It is interesting to note that only a few years ago one of America's foremost surgeons of today wrote in a *Practice of Surgery* the following: "Aspiration as a curative measure combined with siphon drainage has been recommended by some. It is unsurgical, and even as a diagnostic procedure should not be resorted to until one is quite ready to proceed with the operation. Puncture of the liver for the purpose of locating pus should not be made until after the abdomen or the thorax has been opened, and as regards multiple abscesses little can be hoped for from surgical treatment."

What then is the reason for the drop in the mortality rate aside from the use of emetine? It is the general adoption of that "unsurgical" instrument, the aspirating needle, for diagnosis and treatment.

Sir Leonard Rogers states, "there is probably no serious tropical disease in which so much advance has been made during the last quarter of a century both in prevention and cure as in amebic

hepatitis and its sequel, if not urgently and efficiently treated, liver abscess. The aspiration and emetine treatment is now in general use and the open operation is to all intents and purposes obsolete except under unusual conditions."

Notwithstanding the convincing small fatality rate of those using the aspiration and emetine method, it may still be stated that there are 3 recognized methods of treatment in amebic infection of the liver: (1) medicinal, with intramuscular injections of emetine hydrochloride, to be followed by oral administration of ipecacuanha; (2) aspiration of the abscess one or more times, plus emetine hydrochloride intramuscularly and ipecacuanha orally; (3) incision and drainage of the abscess plus emetine hydrochloride and ipecacuanha.

There are those who believe that aspiration or incision and drainage are quite unnecessary in the majority of patients with hepatic involvement and that emetine injections and ipecac orally are not only sufficient in the presuppurative stage, but also in definitely developed abscess. While no doubt exists as to the efficiency of emetine alone in hepatic involvement, yet it is evident that convalescence is hastened and serious sequelae may be prevented by the addition of operative measures. When once an abscess has developed, convalescence will be greatly hastened by relieving the patient of the more or less toxic abscess fluid, which would otherwise be slowly absorbed or encysted.

While no doubt exists that large abscesses do disappear quite rapidly following emetine injections in patients who have refused operation, yet such routine methods of treatment should not be considered proper. It would seem better to reserve

*From the Surgical Service, U. S. Marine Hospital, Baltimore, Md. Submitted for publication November 7, 1929.

the medical treatment, so-called, for the patient who comes for treatment while the hepatic involvement is still in the

The accompanying radiographs illustrate a liver abscess localized by injection of iodized oil. Following aspiration of four

FIG. 1. Amebic abscess of liver previous to aspiration. Definite pointing of abscess.

FIG. 2. Amebic abscess of liver after aspirating $4\frac{1}{2}$ oz. of pus and injecting 1 oz. of lipiodol. Anteroposterior and lateral views localize position of abscess quite satisfactorily for further aspiration or for incision and drainage.

presuppurative stage or for the patient with multiple small abscesses where open operation and drainage are hopeless as regards satisfactory drainage. The early recognition of a presuppurative amebic hepatitis is imperative if later suppuration is to be avoided by the use of emetine and epecacuanha.

The success of operative treatment of amebic abscess of the liver depends upon the ability to bind the abscess or abscesses and to remove the contents either by aspiration or by incision and drainage.

Even after aspiration has been successfully done once, there may be considerable difficulty in finding again the abscess cavity for subsequent aspiration although one may have a general idea of the depth and the relative direction in which the needle first found amebic pus. The use of some opaque substance for injection into the cavity following aspiration of the amebic pus before altering the position of the needle, and subsequent radiographic examination of the liver region in two planes, establishes quite satisfactorily the position of the abscess for future operative procedures.

and a half ounces of chocolate amebic pus, one ounce of iodized oil was injected into the partially collapsed abscess cavity through the aspirating needle. Radiographs were then immediately made in the anterior-posterior and the lateral views. Radiographs repeated two days later showed almost complete disappearance of the iodized oil, apparently due to absorption.

Aspiration, singly or repeated, plus the intramuscular injections of emetine, offers the most satisfactory results and is a life-saving procedure. Under such treatment the mortality has been reduced from far above fifty per cent to less than five per cent. Chatterji has even reduced his fatality statistics in 186 cases to less than two per cent, by the general adoption of the aspiration and emetine method of treatment.

The average patient with amebic abscess of the liver is in an exhausted condition and cannot bear well the shock of an open operation. Aspiration on the other hand usually can be done under a local anes-
the-

sia and is relatively free from shock. The absence of shock following aspiration accounts for a large percentage of the

of benefit while incisions with drainage will certainly result in secondary infection and prolonged suppuration.

FIG. 3. Lateral view showing abscess after injection of 1 oz. of iodized oil into cavity. Its position in relation to sternum and vertebrae is definitely outlined.

decrease in the fatality rate, but also to be considered is the avoidance of a prolonged convalescence due to prolonged suppuration which is exhausting and increases the mortality in those who have stood the shock of open operation.

Since between 80 and 90 per cent of amebic abscesses are sterile as far as pyogenic organisms are concerned, aspiration gives little chance for secondary infection, although secondary infection is practically unavoidable following an open operation and drainage. It should be remembered that a large amebic abscess of the liver offers a favorable medium and optimum temperature for the growth of organisms is introduced by the aspirating needle or subsequent to incision and drainage.

The treatment of amebic abscess should differ little from that given tuberculous abscesses elsewhere. In both conditions one expects to find an abscess fluid sterile as far as pyogenic organisms are concerned. And in both conditions, aspiration will be

FIG. 4. Drainage of liver abscess by anterior incision. Immediate results satisfactory but hernia in epigastric region followed and dense adherent scar formed between abdominal wall and anterior surface of liver, over an area 4 in. in diameter.

The open operation, that is, incision and drainage, has a definite place in selected cases of amebic abscess. If cultures of aspirated pus show pyogenic organisms, incision and drainage will probably be found necessary. If in spite of repeated aspirations the temperature remains septic, and the leucocyte count remains high, incision and drainage may be the only procedure which offers hope. The location of the abscess may determine the method to be followed. Open operation may be indicated in abscesses of the left lobe of the liver and in those of the epigastric region because of the danger of injury to large vessels or abdominal viscera from attempted aspiration without incision. Open operation is also indicated when rupture of the abscess occurs into the pleural or peritoneal cavity and secondary infection occurs. The indications for open operation are as follows: Those

patients showing continuation of acute symptoms which have not been relieved by aspiration plus emetine should have the

FIG. 5. Amebic abscess of liver due to *entameba histolytica*. Abscess involved entire left lobe of liver with hardly more than liver capsule about it. Patient died of suppurative pericarditis due to direct extension or to small rupture through pericardium. At post-mortem examination no rupture could be found.

benefit of an open exploratory incision, although it should be carefully considered that the immediate shock will be severe, and that secondary infection will probably result, that convalescence will be prolonged and that the subsequent exhaustion will carry off some who were able to withstand the shock of the operation. The open operation should be necessary in exceptional cases, as statistics show that the abscess will be found in the right lobe in over 80 per cent of cases, in which case the abscess can be aspirated safely with the aspirating needle.

The signs and symptoms may give definite indications of suppuration and definite signs of localization. Frequently however suppuration is present without certain evidence of localization. The diagnosis must be confirmed and the first treatment rendered by the aspirating needle. The importance of a thorough knowledge of the anatomy in the normal, as well as a visualization of the altered anatomical relations resulting from the hepatitis, must be kept in mind. The point at which the aspirating needle is inserted depends upon the probable location as determined by the localization of pain and tenderness and by signs of localization

as revealed by the roentgen ray picture. If no localizing signs can be found the needle should be inserted in the eighth or ninth intercostal space of the right side and at least five regions of the right lobe explored before giving a negative report. This should be repeated a few days later if the symptoms continue. It is seldom necessary to have a needle longer than four inches, and except in a large individual, the insertion of a needle deeper than four and a half inches carries with it a risk of injury to important structures. Infiltration anesthesia is needed only for the chest or abdominal wall as the patient experiences very little pain when the liver itself is punctured.

When the abscess is located, aspiration may be done with a large glass syringe, by a Potain aspirator or by connecting the needle to a rubber tube running to a water pump or other suction apparatus. While some advise the injection or irrigation of the abscess cavity with quinine or emetine solution, there seems to be no indications for such procedures.

If open operation seems indicated the position of the abscess determines the site of incision. If localized in the right lobe it is accessible by the transpleural route, with or without rib resection. If the signs and symptoms point to suppuration in the left lobe or near the midline, a median incision will give the safest and best exposure.

Whether repeated aspirations or aspiration followed later by incision and drainage is the method of treatment decided upon, the definite localization of the abscess cavity by injection of iodized oil is a valuable aid for future use and may be a time-saving and shock-preventing measure. It is evident from observations made possible from the injection of the iodized oil, that collapse of the cavity apparently occurs as the pus is aspirated. Figure 1 shows a cavity now only large enough to contain approximately 1 ounce, which originally held only a few moments before $4\frac{1}{2}$ ounces. This collapse is probably due to the formation of a vacuum

as the pus is withdrawn, with resulting diminution in the size of the cavity. This would probably not occur in open operation. Rapidity of absorption from the abscess cavity was determined by the repetition of x-ray pictures forty-eight hours later. After forty-eight hours only a small indefinite shadow remained to show the position of the ounce of iodized oil which had been injected, the remainder of the oil, to all appearances, having been removed by the hepatic ducts.

Whatever operative procedure is determined upon, the necessity for intramuscular injections of emetine hydrochloride in one grain doses before and during convalescence is essential. Daily intramuscular injections of emetine in one grain doses for the first ten days, half grain injections for four more days and one grain injections at weekly intervals for four more weeks with careful observations for evidences of toxicity, should result in continued improvement. While there may be some danger of emetine poisoning, amebic abscess of the liver is a dangerous condition and requires the administration of the emetine to the upper limits of safety. Ipecacuanha orally should be administered. Emetine bismuth iodide or other preparations of ipecac may be found less disagreeable by the patient following the administration of emetine and after the acute stage is past. Strovarsol, treparsol, yatren and other preparations have found favor with some and may be useful in resistant cases.

Recurrences of amoebiasis and of hepatic abscess are common. The absence of ameba or of cysts in the stools is not sufficient evidence of complete recovery. There is no more reason to hope that a case of long-standing amebic infection is cured by one course of emetine than that a case of long-standing syphilis is cured by one course of antiluetic treatment. The repetition of courses of emetine hydrochloride in 1 grain doses intramuscularly or ipecac in 30 to 40 grain doses orally is of importance at intervals over a period of months, if future hepatic and

intestinal symptoms are to be prevented; just as in syphilis a small percentage of patients will be found in whom the treatment has no lasting benefit and where relapses will occur.

SUMMARY

In amebic abscess of the liver the two procedures, emetine without drainage, and incision and drainage, have a definite place in a small percentage of cases, yet the routine adoption of aspiration plus emetine, unless contradictions are present, is the most satisfactory method both from the surgeon's and the patient's viewpoint, and is a life-saving procedure.

The use of iodized oil for injection into the amebic cavity immediately following aspiration definitely localizes the abscess, giving its relations to other anatomical parts and making later aspiration or later incision and drainage much easier. The importance of immediate roentgen-rays in two planes must be emphasized, as the iodized oil may not be visible after forty-eight hours.

It is important that emetine and ipecac not only be given during the acute stage, but during and following convalescence if recurrences are to be avoided. The absence of ameba or cysts in the stools cannot be taken as an index of cure in hepatic involvement of the liver, and treatment should be continued at intervals over a period of months.

EARLY SYMPTOMS AND DIAGNOSIS OF CANCER OF THE GENITOURINARY ORGANS*

ARCHIE L. DEAN, JR., M.D.

NEW YORK

KIDNEY

ADENOCARCINOMA or hypernephroma, the most common malignant tumor of the kidney, is rarely diagnosed early. Patients remain in ignorance of their condition for long periods because of the remarkably "silent" nature of the disease. Though the growth may be developing steadily, the excretory function of the kidneys may continue undiminished for years. Relative inaccessibility of the organs prevents a prompt recognition of an early alteration of form.

Sooner or later, however, in the great majority of cases the renal pelvis is invaded, and when ulceration takes place hematuria follows. This is the first symptom in about 85 per cent of all cases. It is at this time that the true nature of the disease should be discovered.

The initial symptom in other cases may be (1) pain in the kidney region; (2) discovery by the patient of a large tumor on one side of the abdomen; (3) loss of weight and strength; (4) discomfort caused by metastases.

Hematuria in these cases may be painless, associated with no localizing sensations. Often however, when blood clots form, there is spasm of the ureter of the affected side and the symptoms simulate those of a ureteral calculus in passage. Again, if a clot occludes a ureter, dilatation of the renal pelvis causes a characteristic unilateral pain in the flank. As relief follows promptly when the clot is evacuated into the bladder, hydronephrosis may be suspected. A clue is furnished if a pipe-like clot, formed in the uterine lumen, maintains its integrity after passage through the urethra.

The usual patient is an elderly person in depreciated general health. Palpation

of the abdomen reveals frequently an enlarged kidney. This finding is substantiated when a roentgenological examination is made in search of demonstrable calculi.

A careful cystoscopic examination is necessary in all cases. Even when the diagnosis can be made on the basis of an enlarged kidney in a patient suffering with hematuria, one should employ the cystoscope to learn the functional capacity of the sound organ. A common problem is presented by those patients who complain of hematuria without any localizing symptoms or signs.

Cystoscopy reveals usually a normal bladder and trigone. Occasionally this cannot be demonstrated until after the evacuation of blood clots. In rare instances the tumor sends an extension down the ureter without involving its walls. If this projects from the ureteral meatus it may be visualized as a pale, cylindrical protrusion. Should the patient be bleeding at the time, the task of the examiner is simplified because red jets will be seen issuing from the ureter of the affected side. Gentle catheterization of the ureter should be performed and specimens of urine collected from each kidney. Finding a few red cells blood is of no moment, but it is significant if trauma by the catheter causes appreciable hemorrhage, or if there is unilateral pyuria or subnormal urea output. It should be born in mind that renal calculi and hydronephrosis may coexist with a tumor, and that a bloody urine observed spurting from a ureteral meatus may contain pus cells from a tuberculous infection.

Searching the stained sediment after centrifugalization for tumor cells is fascinating but fraught with diagnostic pitfalls.

* From the Department of Urology, the Memorial Hospital, New York. Read before the Section of Genito-Urinary Surgery, New York Academy of Medicine, November 21, 1928.

Positive findings by even the most expert cytologist may be erroneous. The writer needlessly removed a kidney, the source of slight bleeding, because tumor cells had been found in the stained sediment. All precautions had been taken to avoid error. The catheters had never been used previously and the report was given by a pathologist of eminence. Serial sections of the kidney were required to demonstrate a tiny area of adenoma of the lowest grade of malignancy.

The excretory function of the kidneys should be studied individually after the intravenous injection of phenolsulphonethalein. Early in the course of the disease there is no diminution in dye output. Somewhat later the output of the affected organ is decreased. Total output usually is normal because the sound kidney increases in function as rapidly as disease destroys its mate.

The pyelogram furnishes data of the greatest diagnostic value. The natural tendency of adenocarcinoma of the kidney is to invade the pelvis. For this reason the pyelogram shows a filling defect of greater or less degree in most cases. Early there may be nothing more than a distortion of the pelvic outline. Later, tumor tissue fills the pelvis, in some cases so completely that the contrast medium can be distinguished only when the roentgen rays strike the fluid tangentially.

After the renal tumor has been revealed roentgenograms should be employed in a careful search for metastases. These occur most frequently in the lungs, long bones, especially of the lower extremities, and bony pelvis. From a point of origin in the medulla the metastasis develops relatively rapidly and with remarkable invasive qualities. Its extension is characterized by complete bone destruction. If the end of a long bone is involved, the process may extend into the joint and through it, involving adjacent bones and even soft parts by direct extension. Metastasis to the lungs through the blood stream gives the roentgenological features noted in metastases from osteogenic sarcoma.

BLADDER

The symptoms of carcinoma of the bladder are usually well marked though not specific in this disease. More than 80 per cent of our patients were performing their usual duties with no premonition of illness when they were startled by the knowledge that they were voiding bloody urine.

No one can emphasize the fact too thoroughly that the symptom of hematuria is positive evidence of organic disease somewhere in the genitourinary system. In every case all proper diagnostic measures should be persisted in until the source of the hemorrhage has been discovered. With competent urologists available to nearly all, a physician assumes an unjustifiable responsibility in prescribing a urinary antiseptic and a period of observation. Only too often the hematuria stops promptly, the patient becomes reassured, but the cancer continues its development.

Coincident with hematuria in some cases, later in the majority urinary frequency is noticed. Before long dysuria sets in.

This sequence of symptoms occurs because the tumor originates in the bladder, most frequently at the base, and continues to develop until its growth at some point outstrips its blood supply. Necrosis destroys the integrity of a vessel wall and hemorrhage follows. In the neighborhood of a growing tumor the bladder wall at first is congested. Later it becomes infiltrated by inflammation or cancer. These changes decrease the bladder capacity and heighten its irritability. The earliest pain in the bladder may be caused by infiltration of its wall, infection, or obstruction by blood clots or tumor. At first the pain is noted only when the bladder contracts during micturition.

In a number of cases frequency and dysuria precede the appearance of blood. When this occurs the tumor is found in the neighborhood of the bladder neck. On account of the greater sensitivity of this region, infiltration causes symptoms of irritation to arise before the tumor breaks down and bleeds.

It is not within the scope of this paper to consider the symptoms associated with the more advanced disease.

In the examination of a patient the act of micturition should be observed closely. In this way information may be gained as to the degree of obstruction, the intensity of dysuria, the amount of hematuria, the period at which these are at their maximum, and the capacity of the bladder. If the odor of the urine is characteristic of putrefaction, we know that necrosis is taking place. The urine is referred to the laboratory for a complete analysis. However, all of these factors are of secondary importance and of no specific diagnostic value. The bladder base is palpated by rectal or vaginal examination in order to learn whether or not the bladder wall has become infiltrated. Occasionally bimanual touch can detect pericystitis or extension of the tumor into the pelvis.

In practically all cases it is through use of the cystoscope that definite and detailed information is gained. With many patients a cystoscopic examination is difficult. Nevertheless if spinal anesthesia is employed to render the operation painless, and suprarenalin be added to the irrigating fluid to diminish bleeding, a good view of the interior of the bladder may be obtained. Perhaps the most valuable factor in the prevention of hemorrhage is gentle manipulation of the instrument. The amount of residual urine liberated by the cystoscope is a measure of the obstruction at the vesical neck.

The tumor may be either papillary or flat. The usual picture is that of a cauliflower-like projection into the bladder cavity from some part of the bladder base. The lower third of the lateral walls is involved frequently by direct extension. The tumors are single or multiple, and of almost any size. In general configuration a simple papilloma is an elongated process with elongated, pointed villi, growing from a relatively small base. In contrast, the papillary carcinoma is a rounded tumor,

the individual villi of which are rounded or club shaped. The base is broad. In addition, the mucous membrane shows a considerable degree of inflammatory reaction in the neighborhood of carcinoma. Surrounding the tumor base there is usually a zone of bullous edema. This subsides through the various phases of congestion as the distance from the tumor increases. Most papillary cancers are reddish pink, but this is obscured frequently by white fibrinous exudate and grey slough, the latter sometimes impregnated with calcareous deposits. Extensive slough is characteristic of carcinoma.

A tumor on a long pedicle usually is benign. The pedicle of a malignant tumor becomes infiltrated relatively early. This causes contraction and shortening to such a degree that the growth often appears sessile.

Flat carcinomas of the bladder are characterized by extensive submucous infiltration with relatively insignificant surface changes. Often the cystoscopic picture is difficult to interpret. No tumor projects into the bladder cavity. Careful search must be made for greyish or yellowish-white ulcers in a field of intense congestion before a diagnosis can be hazarded.

In every case a biopsy should be performed. It is important to classify the tumors as to type and degree of malignancy. Whenever possible the specimen should be removed from the base of the carcinoma, for it is here only that information can be obtained relative to the presence or absence of infiltration.

The information obtained by cystoscopy is supplemented materially by the cystogram. When the bladder is filled with air and stereoscopic films are taken, a beautiful picture reveals the diseased viscus as a whole. Papillary tumors are seen projecting into the vesical lumen, while the infiltration accompanying the flat type prevents expansion. This is shown by a characteristic deformity.

A search for skeletal metastases should always be made. Usually it is sufficient

to obtain films of the lumbar spine, pelvis and femurs, although we have found secondary deposits in all of the long bones, scapulae and the skull. Metastases from bladder carcinoma are demonstrated as areas of bone destruction. It seems probable that the flat carcinomas metastasize more readily than do the papillary tumors.

PROSTATE

Carcinoma of the prostate rarely occurs in men under forty; nevertheless the possibility of the disease must be born in mind whenever a man of middle age presents urinary symptoms. If rectal examinations were performed periodically upon all men over fifty it is likely that something would be accomplished toward improving the prognosis of the disease.

Prostate cancer is not rare. It comprised 17 per cent of all cases of prostatic enlargement and 4.7 per cent of all urological cases seen by Young. The same authority suggests that four men in every 100 over sixty years of age will acquire the disease.

In the great majority of cases the first symptoms are those of bladder obstruction. They begin most insidiously. In fact the disease may be present for some time without causing any symptoms whatever. If the carcinomatous growth is superimposed upon benign hypertrophy of the prostate, as was demonstrated by Geraghty in 61 per cent of his cancer cases, the symptoms are those of the benign lesion. If the malignant disease occurs alone, symptoms depend largely upon the part of the gland involved.

In most cases nocturnal frequency occurs first. Slowly it becomes more annoying. After a time there is difficulty in starting the stream and the flow of urine can be maintained only by conscious effort. Frequency by day becomes established. The patient sometimes feels that in spite of his efforts to void he is not relieved completely. If nothing is done to improve the situation, dysuria sets in, at first in the bladder region and along the course

of the urethra. Later pain is more constant, low in the back or in the thighs. Occasionally there is hematuria.

The symptoms of frequency, difficult urination and dysuria are the result of an obstruction in the posterior urethra due to the carcinoma, to the associated benign hypertrophy of the prostate, or to a combination of carcinoma and inflammation. Infection of the bladder regularly follows obstruction, and the symptoms are aggravated when this occurs.

Pain low in the back, in the penis, perineum or rectum is caused usually by the presence of a large, congested tumor. When radiation is felt along the thighs, perhaps as sciatica, it indicates involvement of or pressure upon nerves of the pelvis. The localization of pain in more remote parts of the body suggests metastases. It is remarkable how extensive metastases may become without causing pain. We have seen patients with bones literally riddled who felt no discomfort at all.

Extension of the disease involves the seminal vesicles rather early because of compression posteriorly of the fold of dense pelvic fascia (Denonvilliers). In some late cases the growth infiltrates the bladder base, and may progress further, involving the anterior bladder wall. More rarely there is extension into the rectum.

The diagnosis of prostate cancer is made usually by rectal palpation. If the patient is placed in the lithotomy position and a metal sound is passed into the bladder, rectal touch may elicit more information than if the usual knee-chest position is employed. Urinalysis furnishes data of no diagnostic value. The cystoscopic picture is not characteristic although congestion and bullous edema of the bladder base are seen with some regularity.

Most commonly the prostate is large and densely indurated. More rarely the gland is of stony hardness but not especially enlarged. The shape is irregular; few of the normal landmarks persist. Nodules usually can be felt here and

there. Firm pressure causes no alteration in the remarkable fixity of the organ. Above the prostate induration can be detected frequently extending into and involving one or both seminal vesicles and passing laterally in many cases beyond the vesicles into the pelvis.

Such a picture of well established cancer is not an unusual finding when the patient first seeks medical advice. On the other hand, we feel prostates occasionally in which it is impossible by palpation alone to determine the nature of a single small area of increased density. For such cases a biopsy needle has been devised. With this instrument we have obtained positive evidence of value in about 60 per cent of our attempts. Recently, quite by accident, another test was found which may prove useful. Two patients who had prostates typical of benign hyperplasia were treated with high voltage roentgen rays. At the end of six weeks there had been such a reduction of inflammatory swelling that indurated nodules of carcinoma stood out in bold relief.

To complete the examination, films should be taken of the lumbar spine, pelvis and femurs in search of metastases. These lesions appear usually as areas of bone proliferation or increased density. In our experience, hypertrophic osteoarthritis of the lumbar spine occurs in a large proportion of patients who have cystitis as the result of obstruction by a benign hypertrophy of the prostate. In some cases it is difficult to differentiate the roentgenological picture of this disease from the osteoplastic metastases of a prostate cancer.

TERATOID TUMORS OF THE TESTIS

In a disease which may progress so rapidly to a fatal issue it is of the greatest importance that a correct diagnosis be made promptly. It is noteworthy that in our series of 124 cases, 43 per cent consulted physicians within a month of the time the first symptom was discovered. Seventy per cent sought medical advice

within the first six months of the disease. However, the correct diagnosis was made so rarely, and for this reason so much time was lost with ineffective treatment, that when seen first at the Memorial Hospital only 11 per cent were found free from local recurrences or metastases.

The diagnosis of teratoma testis is not an easy one, but it would be made with greater frequency if physicians examined intrascrotal tumors with the possibility of malignant disease in mind. In every case of testicular tumor a careful search should be made for metastases. Conversely, whenever a man presents symptoms or signs suggestive of intrathoracic tumor, or if there is a retroperitoneal mass, or a nodule in the left supraclavicular fossa, the scrotal contents should be examined.

Teratoid tumors of the testis must be differentiated from all other intrascrotal enlargements; but the diseases which resemble them most closely are gumma of the testis, hydrocele, hematocele, and more rarely tuberculosis of the epididymis.

When seen early in the course of the disease the patient is a man usually under forty years of age. He complains of a painless swelling of the testis. Inspection reveals a unilateral enlargement without any visible inflammatory involvement, although if the tumor is large the skin may be tense. There is no apparent retraction or shortening of the penis as is seen so frequently with a hydrocele, due to an elevation of the skin at the base of the penis. Examination with transmitted light reveals the solid nature of the tumor. Palpation discloses a testicular tumor, the epididymis rarely being much enlarged. The shape of a normal testis is maintained usually, owing to the density of the tunica albuginea. The consistence in general is firmly elastic, but on account of variability in the make-up of the tumor, some portions may be stony hard, indicating cartilage or bone, while elsewhere the fingers may sink into cystic depressions. In some cases fluid is present within

the tunica vaginalis and the examination is rendered more difficult. This fluid may be aspirated without danger of disseminating cancer cells provided the tunica albuginea is not punctured. A bloody fluid indicates that the epididymis has become involved because hemorrhage of the testicular tumor is confined within the tunica albuginea.

At the upper limit of the swelling there is usually a well-defined line of demarcation and an apparently normal spermatic cord may be felt. Very rarely the cord is sausage-shaped owing to direct extension of the disease. If pulsation of the spermatic artery can be detected, the vessel is unusually large, and a malignant tumor may be suspected. The patient seldom complains when the testis is manipulated; even a purposeful squeeze rarely elicits pain.

After the details of the primary tumor have been ascertained, the examiner should palpate the abdomen, especially of the same side, and the left supraclavicular fossa. A pelvic examination per rectum also is necessary.

Gumma of the testis often cannot be differentiated from an embryonal teratoma by the sense of touch. Clues as to the true nature of the condition may be obtained from the patient's history, but we rely especially upon the Wassermann test. With gumma a positive report is almost invariable. Of course a syphilitic may develop a teratoma.

Tuberculosis is predominately a disease of the epididymis. Most commonly there is a swelling of the epididymis in which nodules can be detected. Demonstration of characteristic changes in the prostate and seminal vesicles usually clinches the diagnosis. By contrast, the infrequent teratoma which invades the epididymis is likely to reach larger dimensions in a short time, be free from nodules, and show no marked inflammation or tenderness.

The abdominal metastases of teratoma testis are deeply situated. They feel rounded, solid and immovable, although

sometimes they pulsate with the aorta. They do not conform to the shape of renal or splenic tumors, and cannot be grasped bimanually owing to their fixed retroperitoneal position. Tympany by percussion may be elicited over these masses, and if on the left side, inflation of the stomach covers the swelling.

In addition to a thorough physical examination, a roentgenogram of the chest should be made in search of metastases in the lungs or mediastinum. Such a film may reveal clean cut rounded masses in the mediastinum. These appear to be the result of direct extension of the disease up the prevertebral lymph channels. Metastatic deposits in the lungs are characteristically dense, clean cut, and round or ovoid. The shape indicates invasion by way of the blood stream and their development within veins.

If all other diagnostic measures have been exhausted and doubt still exists concerning the nature of the testicular tumor, it should be subjected to a therapeutic test. An erythema dose of high voltage roentgen rays delivered to the center of the mass causes a rapid regression in the size of the great majority of teratomas. If the tumor is made up of radioresistant adult tissues, there is no appreciable response.

EPITHELIOMA OF THE PENIS

Penis cancers originate almost invariably beneath a tight, redundant prepuce or one seldom retracted and cleaned.

Clinically there are two types of the disease, the papillary and the flat. The latter is deeply indurated. From the histological standpoint, each is a squamous carcinoma.

The papillary tumor takes its origin from single or multiple warty excrescences which grow rather rapidly in size, increase in number, and later become confluent. After a time part of the tumor breaks down forming a necrotic crater. As a result an acrid, foul smelling, purulent fluid is discharged from beneath an inflamed

prepuce. The tumor spreads by gradual involvement of contiguous structures and at the same time it penetrates more deeply.

The flat type, which constituted 56 per cent of our cases, begins as a rounded erosion with slightly elevated edges. It extends laterally. At all stages this tumor is characterized by its dense induration. Ulcers appear as shallow excavations, yellowish in color. A foul discharge is present.

It is noteworthy that although phimosis and chronic balanitis with their attendant irritation have been present for years, when the cancer appears, practically every patient recognizes the condition as something decidedly different, even if its nature is not appreciated. Moreover, in every case in which the growth could be exposed, the area of true epithelioma was quite small when it was noticed first.

In a series of 75 cases, the first symptom of 73 per cent of the patients was a small sore on the penis. Nine per cent were aware of increased irritation soon followed by the appearance of a small sore. Five per cent suffered from paraphimosis, circumcision revealing a carcinoma. Five per cent first saw warts beneath a tight prepuce. When leucoplakia precedes cancer of the penis the patients notice an area of "scaly skin" or what appears to be a "corn." Occasionally the first intimation of the disease is a hard nodule situated in the distal third of the penis. When it is impossible to retract the prepuce to afford a thorough examination of the lesion, a dorsal slit or lateral incisions should be made. Care should be taken to avoid cutting through cancerous areas.

Of the more common lesions presenting an appearance similar to that of epithelioma of the penis may be mentioned various manifestations of syphilis, papillomatosis of the penis, granuloma inguinale, and certain chemical reactions such as those caused by bichloride of

mercury or the cresol derivatives. Sometimes it is extremely difficult to differentiate these conditions with certainty, especially when the original appearance has been altered by treatment. For this reason the diagnosis of carcinoma of the penis should be made histologically. We believe that a biopsy, carefully performed with a sharp razor, does little if anything toward hastening metastasis. No doubt in most instances a competent physician can make a correct clinical diagnosis; still the records show that much time has been lost following inappropriate therapy before the nature of the lesion was discovered. Moreover, following Broder's grouping of epithelial tumors, scientific treatment is based upon the intimate details of cellular structure and arrangement. This is revealed only by the microscope.

Metastasis occurs relatively late in the course of the disease, but inguinal adenopathy is a common finding. On account of early ulceration of the primary lesion and its environment of filth, the great majority of patients (85 per cent in this series), present palpably enlarged nodes at their first examination. Inguinal metastases usually can be differentiated from purely inflammatory nodules because of a greater degree of induration in early cases and later, when tumor growth has penetrated the capsule of the lymph node, the secondary cancer is fixed.

TUMOR OF THE BONY THORACIC WALL

ASSOCIATED WITH TRAUMA LITERATURE AND CASE REPORT*

CHARLES BRUCE MORTON, M.D.

UNIVERSITY, VA.

IN a recent paper on thoracic tumors Heuer stated that a total of about 240 cases of tumors of the bony thoracic wall had been reported in the literature. He referred to cases compiled by Parham (1898), Lund (1913), Hedblom (1921) and himself. He gave the following statistical summary:

Nearly 80 per cent of these were cases of tumors of the ribs and 20 per cent tumors of the sternum. One hundred and seventy-seven (86 per cent) tumors were primary; 4, probably primary; 11, secondary to tumors of the breast, and 13, secondary to other primary lesions. Pathologically, from 60 to 65 per cent were sarcomas, from 15 to 18 per cent chondromas and 11 per cent carcinomas. Benign tumors other than chondromas have been rare. A few cases included in the series were cases of inflammatory swellings. The difficulties in diagnosis have been the differentiation between benign and malignant tumors. The difficulties in treatment concern the wide opening of the pleura necessary in resection of the thoracic wall, the involvement of intrathoracic structures such as the lung and diaphragm and the secure closure of the thoracic wound. The operative mortality has been reduced from about 30 to about 15 per cent; in individual series it has been as low as 5 per cent. The late results leave much to be desired. The follow-up is given in only 67 of the entire series.

In the group of cases of malignant tumors there was freedom from recurrence in 19 at the time of the last report; but in only 3 of these did the freedom from recurrence extend beyond a three-year period. In the 3 cases there had not been a recurrence for four, seven and nine years respectively. In the group of patients with chondromas, 30 per cent are reported cured, but in many of the cases the period of observation had not extended beyond two years. It is apparent from this summary that the important considerations in this group of tumors are early diagnosis,

early radical operation and accurate follow-up studies.

In the light of this summary of the subject the following case seems of sufficient interest to merit a brief report.

CASE HISTORY

R. B.: The patient, a colored man aged sixty-three years, entered the University of Virginia Hospital September 11, 1928. The family history was negative. When about thirty-seven years of age he had suffered with shortness of breath for a period of a month or more. At that time a large abscess had appeared on the lower part of his right chest in the posterior axillary line. After it had been opened and a large amount of pus evacuated, he had improved rapidly and soon recovered entirely. Six years before the time of his admission he had fractured some ribs on the right side.

The chief complaint was a large mass on the right side of his chest of three years' duration. He had first noticed it a few weeks after he had received a blow which fractured two ribs at the point where his ribs had been fractured previously. The mass had increased in size slowly and had not troubled him until about four months before the time he came for examination. During that period the mass had enlarged more rapidly and had caused some pain.

Examination revealed a well-nourished colored man. The temperature, pulse, respiration and blood pressure were normal. There was some opacity of the cornea of the left eye. The teeth were badly decayed. The heart and lungs showed no abnormality. On the right side of the chest there was an irregular mass about 10 cm. in diameter and protruding about 4.5 cm. above the surface of the chest. Its center overlay the costochondral articulation of the eighth rib. The tumor was very hard, nodular and firmly fixed to the ribs. About 10 cm. lateral to the outer margin of the mass was the old scar of an incision made into the

abscess already mentioned. Examination of the blood and urine showed nothing abnormal and the Wassermann reaction was negative. Stereo-

it from the parietal pleura without injury to the pleura (Fig. 4). The defect in the chest wall was covered by the flaps of the skin alone and a

FIG. 1. Roentgenogram of tumor, lateral view.

scopic roentgenograms of the chest revealed a mass in the region of the costochondral articulations of the seventh and eighth ribs (Fig. 1). The tumor had expanded within the interior of the thorax and pushed aside the parietal pleura. The appearance of the tumor suggested osteochondroma rather than sarcoma. The patient was advised to have the tumor removed.

On September 14, 1928, I made a transverse, elliptical incision over the mass leaving a small area of skin attached to the growth (Fig. 2). Dissection revealed a mass which was an integral part of the seventh and eighth ribs. To remove the mass it was necessary to resect portions of the seventh and eighth ribs and their attached cartilages (Fig. 3). The mass projected into the chest cavity for a distance of about 4 cm., but it was possible to separate

FIG. 2. External aspect of tumor after its removal.

small rubber drain was placed in the dependent angle to remain there for twenty-four hours.

The pathological report described a solid, encapsulated tumor which included portions of two ribs and their cartilages. The mass measured $11 \times 10 \times 9$ cm. Microscopically

FIG. 3. Intrathoracic aspect of tumor.

the tissue was an osteochondroma. It contained quantities of calcium and apparently arose in the costochondral junction (Fig. 5). The postoperative convalescence was entirely uneventful and the patient returned to his home on the twelfth day after operation. The wound had healed completely.

A follow-up letter was answered by the patient November 9, 1929, more than a year

after excision of the tumor. He stated that he was enjoying good health and that there had been no recurrence of the tumor.

formation may exist in certain cases but discredits the majority of such supposed cases and states five postulates which must

FIG. 4. Cross section of tumor. About one-third of the mass was within the thorax. Note the costochondral junction.

DISCUSSION

This tumor of the bony thoracic wall is of particular interest from the standpoint of etiology. Six years before the patient entered the hospital one or more ribs had been fractured at the site in which the tumor subsequently formed. Three years before his admission the same ribs had been fractured again and it was shortly after the second fracture that he first noticed the mass.

The relationship between trauma and the formation of tumors has been the subject of widespread discussion among pathologists for many years. An admirable review of the literature on the subject was made by Knox who concluded that a causative relationship between a single trauma and tumor formation had never been completely established. She mentioned the fact that it has never been possible to produce a malignant growth experimentally in animals by a single trauma.

Williams admitted the possibility of an osteochondroma arising from the cartilage cells in the callus following a fracture. Ewing apparently believes that a causative relationship between trauma and tumor

FIG. 5. Anteroposterior roentgenogram of tumor after it had been removed and sectioned.

be fulfilled in order to predicate a relationship:

1. The authenticity and sufficient importance of the trauma must be established.
2. The previous integrity of the wounded part must be established.
3. A reasonable time relationship, from three weeks to three years, must have existed.
4. The identity of the injured area with the site of the tumor must be established.
5. The tumor, microscopically examined, must be of a type that reasonably could be caused by trauma. Dermoids and other tumors arising from cell rests and so forth are thereby excluded.

The case herewith reported seems to fulfill the postulates. The facts stated in the history were volunteered and no factor of personal aggrandizement or compensation was present to vitiate the reliability of the statements.

That trauma, however, cannot bear more than a predisposing or secondary relationship to tumor formation is demonstrated by the fact that all trauma is not followed by tumefaction and that not all

tumors are preceded by trauma. In this case the trauma which fractured the rib or ribs at the costochondral junction may have displaced some cartilage cells which, when removed from their normal environment of restraining membrane and pressure relationships, commenced to grow unrestrainedly and finally formed the large tumor.

A somewhat analagous sequence of events seems to occur in the juxta-epiphyseal osteochondromata which occur along the ends of the shafts of the long bones, especially the femur, humerus and tibia. As the bone formation of linear growth at the epiphyseal line progresses, small islands of cartilage cells become stranded along the shaft and continuation of unrestricted development in these islands causes the formation of osteochondromata at the site. Ewing recognizes such tumors. In a recent article by Miller and Roberts the sixth illustration depicts a characteristic tumor of that type on the upper part of the humerus.

In this instance, repeated fracture of the rib or the separation of the costochondral articulation may have merely overstimulated the normal processes of repair in some such manner as to cause tremendous proliferation of tissue and the formation of the tumor.

Four months prior to the time of examination the tumor had begun to grow more rapidly. What the stimulus was can be no more than a conjecture. That it may have been a preliminary stage to the develop-

ment of malignant cells within the tumor must be considered, although no evidence of malignant change was found grossly or microscopically. The importance of prompt excision of such tumors of the bony thoracic wall is emphasized by this consideration and also by the extent to which the mass had invaded the chest cavity. Had the parietal pleura been intimately enough adherent to the tumor to necessitate entering the pleural cavity to excise the growth, the operation would have been much more hazardous than the extra-pleural excision proved to be.

SUMMARY

A brief statistical summary of tumors of the bony thoracic wall was given. The history of a case of osteochondroma of the chest wall was reported briefly. In this case there seemed to be a rather definite causative relationship between a single trauma and the formation of the tumor. Some literature on the subject was quoted and the case was discussed from that standpoint. The importance of prompt early excision of such tumors was mentioned.

PERIARTERIAL SYMPATHECTOMY IN CIRCULATORY DISTURBANCES OF THE EXTREMITIES*

CHARLES C. GREEN, M.D.

HOUSTON, TEXAS

IN 1921 there appeared an article by Lariche,¹ reporting his results from periarterial sympathectomy in 100 cases. In 1924 Arthur W. Allen of Massachusetts General Hospital published his results based on a smaller group of cases. Both of these reports were rather sanguine in their tone and gave the impression that much good could be expected from this new procedure.

Following these articles there was a mad rush on the part of many surgeons to use this method in treating all kinds of circulatory disturbances which included causalgia, painful amputated stump endarteritis, traumatic contractures, trophic ulcers, edemas and various ischemic sequelae. And, as a natural course of events, a widespread discussion on the circulation and vasomotor fibers to the extremities, was provoked, which resulted in the development of two schools.

The first group believed that the principal sympathetic nerve fibers accompany the main arteries which supply the extremities and form a network around them in the adventitial layer.

The second group believed that the sympathetic nerve fibers accompany the main nerve trunks which supply the extremities. Thus we have an apparent contradiction but not a real one, as it is an accepted fact that both of these sets of sympathetic fibers supply the extremities, and in order to get the best results a periarterial sympathectomy and nerve stretching must be done.

So numerous are the causes of leg ulcers such as eczema with its cutaneous and fat atrophy, infected ulcers following scratches, tuberculosis and lues, and last, but by no means least, trauma in the presence of varicosities, that the profession

has simply classified them as chronic ulcers without considering the underlying pathology. One only has to read of the myriad of methods suggested for the relief of these conditions, along with the categorical statements of the marvelous and everlasting cures recorded by one group of surgeons and the absolute failures, with the same methods, reported by other surgeons, to realize the chaos which exists at present in the treatment of so common a disease which seems to resist all human efforts.

There are several facts, however, which contribute to our failure in these cases. First, a disinterested and discouraged profession. Leg ulcers constituted no mean percentage of cases in the clinic while we were medical students. The greater portion of them were still uncured when we finished the course. What effect does this have on our profession? Those whom we looked to for instruction failed in their efforts to conquer this disease, with the result that in our subconscious minds we were fully convinced that such conditions could not be cured. We have continued treating them just as was done in the clinics, and with the same results.

Another cause of failure in the treatment of these ulcers is the fact that the underlying pathology has not been considered. We have failed to recognize the fact that all ulcers do not arise from the same cause. For example, one cannot expect to cure a luetic ulcer of the leg simply by increasing the blood supply to this part. Nor can one expect this operation to regenerate the walls of arterioles and capillaries when there is complete organic degeneration of the vessel walls.

But there are two types of ulcers in which this operation will definitely help,

¹Lariche, *Ann. Surg.*, 1921.

* Read before the Texas Surgical Society. Submitted for publication October 3, 1929.

namely, eczematous and varicose ulcers. Here there is no organic destruction in any part of the arterial blood system, but the pathology is in the venous system. So if we can increase our visat ergo and get an increased supply of fresh blood to the parts, we have reason to believe that the ulcers will heal. And this operation does supply fresh blood to the affected parts.

A brief discussion of the technic of this operation will demonstrate the means by which the operation produces a cure.

After preparing the extremity, we make an incision through the overlying structures to expose the vessel. Inspection readily demonstrates a thin covering around the vessel which contains the sympathetic fibers supplying the artery. This tissue is dissected away from the walls of the vessel around its entire circumference and for a length of about two inches. When sufficient amount has been removed the vessel wall has a glistening appearance. The first effect upon the vessel is a constriction which is very apparent during the operation. But this is temporary and is termed the "primary reaction" and is followed in a few hours by a dilatation of the artery, terminal arterioles and capillaries resulting in a definite arterial hyperemia which persists for a period varying from a few weeks to several months.

This hyperemia changes the appearance and condition of the limb from a cold blanched extremity to a warm pink one, in just a few hours. And the change is very apparent and definite.

We have used this method in a limited number of selected cases, but the results have been so satisfactory that the author wishes to make a preliminary report on his primary results and at a later date give you the end-results after a sufficient length of time has elapsed to enable him to determine whether the ulcer will return or not.

CASE I. White woman, fairly well nourished, consulted us for bilateral varicose leg ulcers which had resisted all treatment for six years. She had used all kinds of treatment including rest in bed, but the ulcer would heal

up to a certain point or would heal entirely, only to break down again when she got up and about. On January 25, 1928 a periarterial sympathectomy was performed on the right femoral. The characteristic changes appeared in a very few hours and on about the fourth day the granulation took on a red firm healthy appearance. No further treatment was instituted; only a vaseline gauze was applied every second day. By the end of four weeks the ulcer was entirely healed over.

On February 29, 1928 the same operation was performed on the other side and the progress of the case was the same as in the other leg: the ulcer was healed over in four weeks. This patient was kept in the hospital, made to walk around without any dressings and left the hospital seventy days after the last operation, with both legs healed over. A report sixty days later states that her legs are still perfectly well and she is able to go on with her house work.

CASE II. White man, varicose ulcer of one leg, five years' standing, with same history of having had all kinds of treatment including skin graft. His ulcer was deep. A periarterial sympathectomy was performed on him and in six weeks his ulcer was healed over. He left the hospital sixty days later without his ulcer. He was a regular attendant at the clinic but since he left the hospital we have heard nothing from him nor has he returned to the clinic, so we judge he has had no further trouble.

CASE III. A white woman with a large varicose ulcer of leg was given the same treatment, with the same results. She left the hospital in four weeks entirely cured. There was no subsequent report from her.

While we admit that such a small number of cases can not be taken as conclusive evidence that this operation is the treatment of choice in leg or arm ulcers, still our results have been so uniform and so perfect that we felt it worth your while to listen to our preliminary report of these cases.

We shall attempt to get in touch with these cases at a later date and also to get new cases and give you more information regarding the final outcome of these cases sometime in the near future.

TREATMENT OF DIAPHRAGMATIC HERNIA*

LEIGH F. WATSON, M.D.

LOS ANGELES, CALIF.

IT IS only in recent years, with the improved methods of diagnosis, that nonstrangulated diaphragmatic hernia has been recognized early and treated by operation, resulting in the development of a successful surgical technic.

On account of the severity of the symptoms and the danger of strangulation, the radical operation by the abdominal route is the treatment of choice. The thoracic route is preferred by a minority of surgeons. When it is impossible to reduce the hernia from the abdominal side, it is necessary to make use of both incisions.

THE ABDOMINAL OPERATION

The abdominal route is indicated when there has been injury to abdominal viscera and when there are symptoms of intestinal obstruction. It enables the operator to confirm the diagnosis promptly and in case intestinal resection is necessary, it affords the better exposure and permits a quicker repair. The patient suffers less from shock following laparotomy than after thoracotomy.

The patient is placed in the Trendelenburg position and the abdomen opened by an incision above the umbilicus in the midline, or by a lateral rectus incision, or by one of the gallbladder incisions. A free exposure is essential, and it is often advisable to carry the incision one or two inches (2.5 to 5 cm.) below the umbilicus.

On opening the abdomen, the operator will immediately notice that certain of the viscera are not in their normal position; the organs most frequently herniated are the stomach, transverse colon and small intestine. With the patient thoroughly relaxed under general anesthesia, the hernial opening in the diaphragm is exposed by wide retraction, and the hernia reduced by grasping the portion of viscera

still within the abdomen and making gentle traction on it; reduction may possibly be facilitated by placing the patient in a vertical position. If reduction cannot be accomplished, the hernial opening can be enlarged; this failing, it is necessary to open the thoracic cavity, free the adhesions and reduce the hernia. In Scudder's patient, a stomach tube was passed and the viscus emptied by compressing it in the chest; the hernia was then reduced without difficulty. Mayo passes a rubber tube into the chest through the hernial opening to relieve the suction force of breathing.

The principal disadvantages of the abdominal route are, the depth of the hernial opening, the impossibility of freeing extensive adhesions in the thorax, and the difficulty of preventing the viscus in the hernia from being drawn back into the chest with each inspiration.

The method of closure of the diaphragmatic opening depends on its size and location. If the edges of the opening can be brought together, the hernia can be closed with interrupted or mattress sutures of heavy chromic catgut, taking a deep bite in the muscle with each stitch; this closure can be reenforced by a second layer of sutures, either continuous or interrupted. Soresi closes these openings by taking a number of stitches on each side, parallel to the edge of the opening; these stitches are tied together on each side and then tied across, leaving a small opening at each end to be closed by purse string sutures.

If drainage of the pleural cavity is necessary, it can be secured by making a stab wound, with a sharp-pointed hemostat, passed through the diaphragmatic opening, and through the posterior part of the chest wall between the ribs, at the lowest point of the pleura. The line of suture of the diaphragm is often reenforced

* Submitted for publication November 9, 1929.

by sewing a strip of fascia or a portion of the omentum or stomach, which has been in the hernia, to the edges of the opening.

FIG. 1. The combined thoraco-abdominal incision for diaphragmatic hernia. The 6th and 7th ribs are shown resected. (a) The pleural cavity. (b) Line of skin incision. (c) The abdominal cavity.

If the hernia cannot be reduced, and the condition of the patient does not permit opening the thorax, a gastrojejunostomy can be done; if the transverse colon is in the hernia, the ascending and the descending colon can be anastomosed.

THE THORACIC ROUTE

The thoracic operation should be used when there is traumatic injury of the pleura, lungs, heart or blood vessels, accompanied by hemorrhage. The wound in the chest acts as a guide down to the hernia, which can be freely exposed simply by enlarging the wound.

The advantages of the thoracic route are: It is easier to deal with the hernia because it is nearer the surface than when approached from the abdomen; the hernia can be more readily reduced, and the adhesions to the pleura and pericardium can be freed; and it is less difficult to close

the hernial opening. If gangrene has already occurred, the thoracic route should be used first, because of the chance of perforation having occurred, and the danger of tearing the viscera in reducing the hernia. The abdominal viscera should be examined and treated through a laparotomy incision.

The patient is usually placed on the table in a lateral position. The intercostal space is widened by means of a pillow or sand bag under the chest. The incision is made in the eighth or ninth intercostal space and is 4 to 5 inches (10 to 12.5 cm.) in length. Strong retraction is made and the ribs widely separated. It is usually possible by this means to avoid the resection of one or more ribs. If the exposure is insufficient, it is necessary to resect the costal arch.

I believe that the best exposure is obtained by an incision which begins at the lower edge of the rib at the end of the xiphoid cartilage, divides the rectus muscle, and enters the intercostal space between the ninth and tenth ribs without opening the pleura.

The hernia is reduced, the excess of sac is folded upon itself and used as a pad to close the opening, or the sac can be resected and the edges overlapped and sutured. The edges of the hernial opening are brought together by interrupted sutures of heavy chromic catgut, or one of the methods of closure used in the abdominal operation can be used here.

When the opening in the diaphragm cannot be closed by ordinary means, it can be accomplished sometimes by resecting the ribs in front of the hernia. The danger of pneumothorax is generally overestimated; if the chest is opened gradually, the symptoms are slight. A differential pressure cabinet is unnecessary. If dyspnea appears during operation, the lung should be drawn down to the wound and steadied with a soft rubber covered forceps. Before completing the operation, one should insert into the pleura a small blunt trocar attached to a syphon bottle. At the

completion of the suture all the air in the chest can be readily aspirated, and the lung reexpanded.

If the chest has been opened under local anesthesia, the patient can be allowed to come out of the general anesthetic as soon as the diaphragm is closed; with assistance, he can close his mouth, hold his nose, and by blowing, expand the lung as the final suture is tied. If there is danger of infection, or if there has been an extensive separation of adhesions, a drain can be left in the pleura; however, when possible, the wound should be closed without drainage.

THE COMBINED THORACO-ABDOMINAL OPERATION

The combined operation is the treatment of choice in a great many cases; it is being used with increasing frequency. Often it is necessary to open both the thorax and the abdomen, to reduce the hernia and to deal with complications. Some operators prefer to open the thorax and then the abdomen by separate incisions; others use the single incision which exposes both cavities simultaneously.

Schwartz and Quénu recommend the combined thoraco-abdominal route in all cases. The incision begins in the axillary line and extends forward in the seventh intercostal space. The pleural cavity is opened, care being taken to avoid a too sudden pneumothorax or injury to hern-

iated viscera that may be adherent to the chest wall. The incision curves downward over the rectus muscle to the midline, and then down to the umbilicus. The peritoneal cavity is opened; the cartilaginous portion of the ribs, at the site of incision, is cut with scissors; and the incision continued in a straight line through the diaphragm to the hernial opening. The adhesions are separated, the viscera reduced, the margins of the opening freshened and sutured, the cartilaginous edges brought together and the wound closed. If necessary, a drain can be left in the lower part of the pleural cavity for two or three days. Auvray resected the ninth rib and continued the incision down to the umbilicus. He cut through the ninth costal cartilage and incised the diaphragm up to the hernial opening. The hernia is reduced, the opening sutured, and the wound closed.

CRANIOCEREBRAL INJURIES*

JOSEPH F. DOUGHERTY, M.D.

UPPER DARBY, PA.

CRANIOCEREBRAL injuries are of very frequent occurrence. They make a large percentage of the accident work admitted to a general hospital. The group of 25 cases which I am reporting were consecutive admissions to the surgical service of Dr. Thomas J. Ryan at the Misericordia Hospital during a period of one year. It is my purpose in this review to outline our mortality, the method of treatment and give a short discussion of the sequelae. We have divided these cases into laceration of the brain and fracture of the skull. Only those cases are reported as fracture which were positive by x-ray findings. The cases which were diagnosed as laceration of the brain were negative for fracture by x-ray examination, but had bloody spinal fluid and alterations in the spinal fluid pressure. The cases were divided as follows:

| | Number | Deaths | Mortality, Per Cent |
|----------------------------|--------|--------|------------------------|
| Laceration of brain. . . . | 9 | 0 | 0 |
| Fracture of skull. | 16 | 4 | 25 |
| Total. | 25 | 4 | 16 |

In reviewing the mortality in the literature during the past few years I find that Stewart¹ reported 617 cases with 322 deaths, a mortality of 52 per cent; McCreery² and Berry report 520 cases with 204 deaths, a mortality of 39 per cent; Djerup³ of Copenhagen reports 57 per cent mortality. It is interesting to note the variance in these mortality figures. The 57 per cent mortality of Djerup is included in this discussion because it is his practice to operate on all cases which present any signs of increased intracranial pressure.

PATHOLOGY

It is necessary to have a definite conception of the circulation of the cerebrospinal fluid in order to manage these cases intelligently. The fluid is secreted by the choroid plexus in the ventricular system and communicates with the subarachnoid space through the foramina of Magendi and Luschka. The fluid circulates in the subarachnoid space and is absorbed into the dural sinuses by the pacchionian bodies which are arachnoid villi projecting into the sinuses.

The early symptoms resulting from head injuries are dependent upon the damage done to the contents of the skull rather than to the skull itself. The injury to the skull is important if the fracture is compound or if it is depressed and causing symptoms. The pathology which exists in the brain varies from contusion and mild edema to petechial hemorrhages and extensive lacerations. There is no organ in the body in which the effects of pressure are so serious as in the brain, owing to the fact that it is confined in a bony case incapable of expansion. It is true that a slight increase in pressure may be compensated for by the communication between the cranial and spinal cavities; but this is limited.

The sequence of changes occurring in the circulation of the fluid as a result of these injuries has been well described by Jackson,⁴ "As a result of trauma a local swelling of the brain soon arises at the site of injury and reaches its maximum in twenty-four to forty-eight hours. If the swelling is slight the interference with absorption of cerebrospinal fluid is only moderate and the intracranial pressure will return to normal in a few days. If, however, the local swelling is more marked the general effects will be more serious."

As the local swelling increases the cere-

* Submitted for publication December 31, 1929.

brospinal fluid is driven out of the cerebral subarachnoid space into the corresponding space in the spinal canal. The brain is pressed against the vault of the skull, the subarachnoid space is compressed and obliterated, and the absorption of the cerebrospinal fluid from that space stops completely. Circulation of the fluid ceases and stasis results. The accumulating fluids in the basal cisterns pushes the brain still more forcibly against the cranial vault, still more effectually interfering with absorption. As the brain is pushed upward the brain stem tends to plug the narrow incisura tentorii, so that the fluid accumulates in the basal cisterns and distends the ventricles, producing a form of communicating hydrocephalus.

TREATMENT

The treatment of these head injuries falls under the ten following divisions:

1. Shock.
2. X-ray.
3. Spinal fluid pressure.
4. Spinal drainage.
5. Glucose 50 per cent.
6. Magnesium sulphate.
7. Neurological consultation.
8. Eye consultation.
9. Otolaryngological consultation.
10. Operation.
 - (a) Compound fracture.
 - (b) Depressed fracture.
 - (c) Foreign body.
 - (d) Extradural hemorrhage.
 - (e) Intradural hemorrhage.

Upon admission the case usually presents symptoms of shock which are treated in the usual manner. No operation is performed at this time unless we feel that the condition present within the brain is adding to the amount of shock. Lacerations are debrided, the bone investigated and the scalp is sutured loosely. The blood pressure is recorded and spinal puncture performed. The spinal puncture is instituted as soon after admission as possible. The spinal fluid pressure is estimated

and the amount of fluid withdrawn is dependent upon this pressure. Frequent pressure readings are recorded during the withdrawal of the fluid to assure of free circulation. If the spinal fluid pressure is increased beyond 30 mm. Hg it is reduced 50 per cent; if it is below 20 mm. Hg it is reduced to normal. The spinal fluid pressure is estimated as frequently as symptoms demand, the attending physician being guided by blood pressure readings, mental condition and pulse rate. However, this reading is estimated at least once a day until the pressure returns to normal. If the fluid is bloody but not under pressure it is removed daily until it becomes clear. X-ray examinations are made as soon as the shock has subsided, although at times we have found it necessary to have this examination performed in order to confirm or outrule the diagnosis of a depressed fracture. Intravenous injections of 50 per cent glucose are given for the purpose of reducing intracranial pressure and at the same time acting as nourishment to the patient during the first few days when he may not be able to take food by mouth.

Magnesium sulphate is also given by mouth and rectum for the purpose of reducing intracranial pressure. Neurological consultation is instituted as an emergency procedure and we are guided to a considerable extent by the decision of the neurologist. We rely almost completely upon the deductions of our neurologist for the institution of operative procedures unless the indications are very evident upon admission, such as a compound fracture, a depressed fracture or foreign body. Eye consultations were originally performed within the first two or three days following admission, but we now find that more information can be gained by having this consultation at a later date. Otolaryngological consultation is always performed in the cases with discharge from the ears, nose or mouth. In regard to the late operations for these head injuries we are inclined to wait until

definite decision has been made by the neurologist.

SEQUELAE

The important complications which occurred in this group were blindness in the right eye in one patient with a fracture of the vault, weakness in the left arm in a patient with a depressed fracture which was operated, and left hemiplegia in a patient with a fracture of the vault. In 12 of these cases we have been able to determine the late symptoms over a period of from one to six months, although we realize that this is a short period of time to judge the late symptoms. We hope in the future to make a further contribution to this subject with relation to these symptoms and the intracranial pressure. Four of these patients have complained of persistent headaches, although they have all returned to the same occupation that they followed before the injury. In examining the literature of the late head symptoms we find that there is not a large group of cases reported. The question might arise as to the wisdom of treating these cases conservatively, but we are convinced from the study of the physiology and pathology of this condition that the treatment should be conservative and operations be performed only after considerable deliberation.

It appears from these reported cases that the late symptoms vary a great deal, but judging from the literature,

better end-results may be expected following conservative management.

| | Cases | Head- aches, Per Cent | Dizzi- ness, Per Cent | Epi- lepsy, Per Cent |
|------------------------------------|-------|--------------------------------|--------------------------------|-------------------------------|
| Jackson ⁴ | 295 | 17 | 4 | 8 |
| Strecker, E. A. ⁵ | 30 | 80 | .. | 23 |
| Hanse, A. ⁶ | 88 | .. | .. | 19 |
| Dougherty, J. F..... | 12 | 33 | 0 | 0 |

CONCLUSIONS

1. Conservatism in the treatment of cranioerebral injuries will probably show the best immediate and late results.
2. The intracranial pressure can in most cases be adequately controlled by the judicious use of spinal drainage in conjunction with a spinal manometer. The manometer should always be used in doing a spinal puncture.
3. A clear understanding of the pathology is necessary for the proper management.
4. Operation should not be instituted unless very definitely indicated.

GASTROCOLIC FISTULA*

BRIEF REVIEW OF LITERATURE AND REPORT OF CASE

MEYER GOLOB, M.D.

NEW YORK

THE condition of gastrocolic fistula, or cologastric fistula as I prefer to call it in my case because the lesion originated in the colon, is sufficiently unusual to justify report of a case. The majority of cases of gastrocolic fistula occur as a sequel to posterior gastroenterostomy for jejunal ulcer. In the case reported, the condition was apparently primary carcinoma of the colon, which formed a fistulous connection with the stomach.

Verbrugge¹ in 1924 collected 202 cases of gastrocolic and gastrojejunocolic fistulae from the literature, including 7 cases previously reported from the Mayo Clinic, and added 14 new cases from the Clinic, making a total of 216. In 95 of these cases, the fistula resulted from a jejunal ulcer following posterior gastroenterostomy; in 121, from a primary organic lesion of the stomach or colon, chiefly carcinoma. The 70 cases reported prior to 1903 originated from cancer of the stomach or colon.

According to recent reports, to quote Verbrugge:

Fistulas due to cancer of the colon and stomach seem to be decreasing, whereas fistulas following gastroenterostomy are increasing. This can easily be explained by the fact that early diagnosis and intervention in cases of cancer of the digestive tract have reduced the number of these large tumors, whereas the more frequent use of posterior gastroenterostomy for gastric, and especially duodenal, lesions has increased the number of jejunal ulcers.

Of the 21 cases of gastrocolic fistula from the Mayo Clinic, 2 were due to cancer of the colon perforating into the stomach; 19 to jejunal ulcer following posterior gastroenterostomy. Fistulae in cases of carcinoma of the colon or stomach, Verbrugge notes, are part of the tumor itself. They are lined with tumor cells.

The most characteristic symptoms of gastrocolic fistula are diarrhea, foul eructations and vomiting of fecal material. Pain is not a usual symptom. Of the 21 cases from the Mayo Clinic, roentgenographic examination was made in 20. The findings were definitely positive for fistula in 11, doubtful in 1, and negative in 8. A clinical diagnosis was made in 13. Seven cases not diagnosed clinically were also not diagnosed by the roentgenographic examination.

Kuttner² in 1926 and Jansson³ in 1928 both noted that roentgenologic diagnosis of gastrocolic fistula can sometimes be made by the use of the opaque enema, when the opaque meal fails to show the condition. By means of the enema, the fistula may be clearly demonstrated and the stomach may be seen to fill rapidly from the colon.

Recent case reports (since 1924) relate chiefly to gastrocolic fistula due to jejunal ulcers following gastroenterostomy. The following cases after carcinoma of the colon are reported:

Dickson⁴ in 1928 reported 6 cases of gastrocolic fistula from the Toronto General Hospital, 2 of which were secondary to carcinoma of the colon:

In 1 case, the patient was a man fifty-two years of age, who, on admission to the hospital, was pale and sallow and complained of diarrhea alternating with constipation. He had had attacks of vomiting for the preceding two weeks, and more recently the odor of the vomitus had become fecal. A barium enema showed that the sigmoid and descending colon filled quickly. There was a circular filling defect in the transverse colon about 3 inches proximal to the splenic flexure. A fistula was demonstrated passing from the upper limit of this defect, through which the stomach was quickly filled. A diagnosis of gastrocolic fistula secondary to carcinoma of the colon was made. Operation was refused, but the diagnosis was later confirmed at autopsy.

* Submitted for publication October 19, 1929.

In the second case, that of a man forty years of age, the patient showed loss of weight, weakness, diarrhea and vomiting. These symp-

FIG. 1.

toms had been progressively increasing for the preceding six months. The vomitus was of the fecal type. A barium enema showed a filling defect in the same region as in the previous case. A definite fistula was demonstrable. It entered the posterior wall of the stomach. A second fistula was found passing into the jejunum. Laparotomy was done, but no repair was attempted, because of the patient's condition. Death occurred within six hours after operation. Autopsy confirmed the diagnosis of carcinoma of the transverse colon with gastrocolic and jejunocolic fistula.

Brock⁵ in 1928 noted that a large majority of cases of gastrocolic fistula follow perforation of a jejunal ulcer after gastrojejunostomy. The second leading cause is malignancy of the stomach or colon. Although gastrocolic fistula is a rare condition, 4 cases were seen by Brock in rapid succession at Guy's Hospital, London. Three followed gastrojejunostomy and 1 a growth of the transverse colon.

In the latter case, the patient was a man thirty-nine years of age. For three months

prior to admission to the hospital, he had lost weight and strength. During this period he had an attack of diarrhea. He had vomited occasionally, the vomitus consisting of undigested food eaten two or three days earlier. Belching of foul gas was also a troublesome symptom. There was no pain, abdominal distention or palpable tumor. The vomiting and belching ceased soon after admission to the hospital. Samples of the vomitus and feces were identical in appearance, both being rancid, dark and fluid, and containing a little solid matter. Roentgenologic examination with an opaque meal showed a communication between the pyloric vestibule and the transverse colon. One opaque enema showed a dilated colon with the fluid passing as far as the middle of the transverse colon and then flowing into the stomach. At operation, the fistula was found; also, secondary carcinomatous nodules on the peritoneum. No attempt was made to excise the fistula. The patient died from bronchopneumonia twelve days after operation. At operation it could not be definitely decided whether the primary growth was in the stomach or in the colon, but at autopsy a large carcinoma of the transverse colon, which had ulcerated into the stomach, was found.

Brock notes that, including the 4 cases reported by him, there are records of 10 cases of gastrocolic fistula at Guy's Hospital. One case, that already reported in detail, followed carcinoma of the colon; 1, gastric carcinoma; and the others, jejunal ulcer resulting from gastrojejunostomy. Brock states that when gastrocolic fistula is due to carcinoma of the stomach of colon it is usually associated with advanced malignancy; but the history may be relatively short and obscure, as in his own case, in which no metastases were found except the secondary nodules on the peritoneum.

REPORT OF CASE

Mrs. E. L., aged forty-nine, was referred to me by her family physician in February, 1929, because of the presence of a definite mass in her abdomen. Her chief complaint was pain in the right shoulder. The family and past personal history was negative, and the present illness was of only four weeks' duration. However, her weight had fallen from 155 to 140 lb. in three months.

The patient was well nourished and seemed to be in good general health. Her breath was

extremely fetid, much more so than could be accounted for by a condition of oral sepsis. It suggested deep-seated putrefaction in the gastrointestinal tract.

There was a definite movable tumor in the left upper quadrant of the abdomen. The diagnosis of a neoplasm was confirmed by roentgen-ray study, which revealed an extensive filling defect in the distal portion of the transverse colon and a fistulous connection with the greater curvature of the stomach. This condition is shown in the accompanying roentgenogram.

Examination of the gastric contents gave normal figures for free hydrochloric acid and combined and total acidity. Lactic acid was negative and no Boas-Oppler bacilli were found.

Hemoglobin was 75 per cent and the red blood cell count in proportion. The urine was negative. Several blood pressure readings showed slight hypotension.

On February 27, 1929, laparotomy was performed at the Mt. Sinai Hospital by Dr. A. A. Berg. His findings corroborated the clinical and roentgenologic diagnosis: There was an adenocarcinoma of the colon with suppuration and a fistulous connection with the stomach through the gastrocolic ligament.

Operative finding: Large tumor in the transverse colon. This tumor had perforated into the mesocolon and omentum. It was adherent to the peritoneum and had ruptured into the stomach, with the resulting formation of a gastrocolic fistula. The colonic tumor was resected after its complete mobilization. The involved portion of the stomach was excised, and end to end anastomosis of the colonic ends and a repair of the defect in stomach was made.

There was an uninterrupted convalescence, the wound healed kindly, and the patient was discharged from the hospital about seven weeks after the operation.

COMMENT

In my opinion, this case represents primary adenocarcinoma of the colon, for the following reasons:

1. The carcinomatous involvement of the colon predominated considerably over that of the stomach.

2. The course of migration of the opaque medium was obviously from the colon to the stomach. After a barium meal, the tortuous opaque streak revealing the fistula was not observed. However, this

finding was apparent after a barium suspension enema when the medium was introduced under pressure.

3. The absence of symptoms referable to the stomach and the normal findings on analysis of the gastric contents indicate the absence of any considerable glandular involvement of the stomach.

To my mind, the extremely short duration of the illness in this case was more apparent than real. Patients of this type have a tendency to minimize their symptoms so as to obscure the real course of the malady. A fistulous tract connecting two adjacent organs through neoplastic tissue could not have been formed in so short an interval as the history might suggest.

The marked fetor oris is apparently to be ascribed to the condition of tissue breakdown associated with the fistulous tract. This case illustrates the general rule that roentgen-ray study is the only means by which exact preoperative diagnosis can be made in cases of gastrointestinal neoplasm and surgical intervention may thereby be rendered less speculative.

SUMMARY

Gastrocolic, or cologastric, fistula is a rare condition. Two hundred sixteen cases were reported up to 1924. In most instances the disturbance is a sequel of posterior gastroenterostomy for jejunal ulcer. It may result from malignancy of the stomach or, as in the case reported, from carcinoma of the colon.

In the case reported, the condition should be called cologastric fistula, because the malignant growth originated in the colon and formed a fistulous tract leading through the gastrocolic ligament to the greater curvature of the stomach. The case occurred in a woman, aged forty nine, who had a definite movable tumor in the left upper quadrant of the abdomen. Roentgenographic examination after an opaque enema under pressure clearly indicated that the course of the fistula was from the colon to the stomach. The findings were confirmed at operation.

MODIFICATION OF THE UNGER APPARATUS

FOR BLOOD TRANSFUSION*

HENRY S. MARTIN, M.D., F.A.C.S.

WARSAW, N. Y.

DURING the past few years several modifications of the Unger apparatus for whole blood transfusion have made their appearance. Most of these changes have not resulted in an appreciable increase in the efficiency, dependability or ease in manipulation of the apparatus.

The apparatus designed by Dr. L. G. Unger of New York City has been, for several years, the favorite apparatus of many surgeons who perform a considerable number of transfusions and who have mastered the technic of its use. In their hands, the method is very dependable. The technic is simple and any desired amount of blood can be transfused with ease and rapidity. However, many competent surgeons who perform a very few transfusions each month, are frequently confronted with at least an occasional failure. In many localities it is unjustly regarded as an impractical instrument.

As regards the original Unger apparatus per se, the principal causes of transfusion difficulties and failures are:

1. The sticking of the Record blood syringe due to the thin film of blood which gradually forms between the plunger and the barrel. This sticking is favored by the unequal heat expansion of the metal and glass and also by the small outlet of the syringe.

2. The small bore of the stopcock connections and of needle adapters retarding the ready flow of blood. Partial clotting is thus more likely to occur with resulting difficulties of withdrawal and injection of blood.

3. The Record blood syringe breaking as a result of falling from the stopcock.

4. The entrance of blood into the saline solution.

It is obvious that the above difficulties could be largely eliminated by:

1. Using a blood syringe having the barrel and plunger of the same material and a larger outlet.

2. Increasing the bore of the stopcock connections and of the needle adapters.

3. Using a bayonet lock connection for the blood syringe.

4. Practically eliminating saline solution.

The apparatus presented here has been satisfactorily used for one hundred transfusions at the Wyoming County Community Hospital. An attempt has been made to eliminate the causes for occasional failures. It is believed that the changes mentioned below have resulted in a more efficient and dependable instrument especially in the hand of the occasional operator.

A Record syringe is used for the injection of saline instead of a glass Luer syringe. Between its connection and the four-way cock, a one-way cock is placed. With one hand the assistant can easily turn the one-way cock and refill the syringe with saline, thus having his other hand free for other assistance such as holding an infant's arm, etc. In case the blood syringe is broken this Record syringe may be used as a substitute by inserting an adapter.

The transfusion syringe designed by Dr. John M. Scannell of Brooklyn is used for withdrawing and injecting blood, instead of a Record syringe. As it is constructed chiefly of glass, sticking of the plunger is lessened. It has a large outlet and is connected to the four way stopcock by a strong bayonet lock. As the metal ring of the Scannell syringe was unnecessary, it was removed. By means of an adapter, this syringe may be used for the injection of saline in case the Record syringe is broken.

* Submitted for publication October 19, 1929.

The bore of all parts (saline connection excepted) of the four-way cock and of the two needle adapters was increased to 2.5

the patient's home. It is perfectly adaptable to the method of blood transfusion as advocated by Dr. O. A. Brines of Detroit.

FIG. 1. Apparatus assembled.

mm. The metal disks of these adapters were increased to 11 mm. to permit a better grasp should the necessity arise of changing the rubber tubing during the course of a transfusion.

When the transfusion is underway satisfactorily the use of saline solution is discontinued. The use of ether spray upon the blood syringe to retard the clotting time and the expansion of the syringe is not objectionable when employed as a very fine spray. The increased bore of the apparatus and the use of the Scannell syringe have practically eliminated the necessity for saline solution and ether except in unusual cases where the actual transfusion time is prolonged.

The apparatus is very satisfactory whether used in the operating room or in

FIG. 2. Apparatus in case.

By the Brines method both syringes are used for withdrawing and injecting blood. A physician or nurse assistant is desirable but not essential to the complete success of the transfusion. A compact wooden case was constructed to house the complete outfit. In the upper half of the case there is ample space for instruments necessary for transfusion.

CARGILE MEMBRANE IN PREVENTING INTRA-ABDOMINAL POSTOPERATIVE ADHESIONS*

GEORGE S. FOSTER, M.D.

MANCHESTER, N. H.

POSTOPERATIVE adhesions are surely a curse to be avoided when possible. How many times we have seen cases of clean abdominal surgery that months after the operation returned complaining of that dull, dragging pain beneath the site of operation, marked constipation and a certain degree of disability.

A careful and thorough physical examination of these cases revealed no new pathology except the possibility of adhesions. Roentgenograms shows that the intestinal tract was bound down, kinked or twisted in certain areas adjacent to the field of operation. This in itself accounts for all of the signs and symptoms found and thus the diagnosis of postoperative adhesions is made.

Few, if any, of these cases reacted satisfactorily to any form of medication or non-surgical treatment. If observed over a long period they would remain about the same. Finally in some instances a secondary celiotomy was advised.

On the table these cases reveal in fact the conditions shown by the roentgenogram. This fact we have faced several times, some of the cases having been previously operated upon by ourselves and some coming from other hospitals. A careful study of these cases during the past ten years has brought into use in our clinic the introduction of Cargile membrane for use in these cases as a preventative of the reoccurrence of these adhesions following their release and the return of the intestines to their normal position and contour.

In the first few cases of its use we found that very satisfactory relief was obtained without the return of the signs and symptoms previously noticed. Carefully observing these first few cases over a period of

one to three years we were quite convinced that the use of Cargile membrane as a routine in covering over any intra-abdominal raw areas left after the operation was completed was satisfactory in preventing these postoperative adhesions.

Again we collected quite a number of cases that had been previously operated upon by ourselves or in other hospitals for an intra-abdominal purulent condition where longer or shorter drainage was necessary to save life. Of course, we would naturally expect these cases to yield multiple intra-abdominal adhesions and later on give the consequent signs and symptoms. In this class of cases we naturally found many more as well and more firm and completely organized adhesions which when released at the secondary celiotomy left many more or less extensive raw surfaces. In this class of cases we also introduced the Cargile membrane to cover over these raw surfaces and found that the results were very satisfactory. In observing this type of case over a period from one to three years we found that the relief to the patient of previous signs and symptoms was most gratifying.

Thus we have by gradual steps come to use Cargile membrane as a routine in all intra-abdominal surgery where even the smallest raw surface is left as a possible modus for the later attachment of the intestine to this surface. This routine we have had in action now for about five years and the cases that return to us with signs and symptoms of postoperative adhesions are very few. In fact, we have had no complaints. Our system now in vogue has as a part the follow-up report covering a period of two years. Thus we can check up fairly accurately.

* Submitted for publication, March 10, 1930.

Of course, it is understood that in the cases which come to us with a purulent intra-abdominal condition cannot, at the

intestinal loops from adhering to a suture line in a gastroenterostomy or an entero-enterostomy.

FIG. 1. Showing kink in duodenum secondary to adhesions.

FIG. 2. Showing cargile membrane C. M. folded about raw area of duodenum.

first sitting, have the Cargile membrane used as it is directly contraindicated. As a matter of fact when used it very early dissolves by chemical, bacterial action and within a few days has disappeared. So, when it is used in these cases, does no good. In this class of cases we warn the patients, when discharged from the hospital, of the possibility of further trouble from postoperative adhesions and recommend that they return at the end of a two-year period for a complete observation and investigation to determine the presence or absence of any postoperative adhesions and the presence of any signs or symptoms as a result of such. If found present and giving any discomfort, we advise readmission for a secondary celiotomy and correction, using the Cargile membrane at this time. By following out this routine and instituting the relief operative measures we find that very satisfactory results are obtained.

In clean intra-abdominal cases such as hysterectomy, cholecystectomy, intestinal resection, strangulated or incarcerated hernias, gastroenterostomy and the like, we always use the Cargile membrane to cover all suture lines and raw surfaces. Thus are prevented coils of intestine from adhering to the raw points in the pelvic floor, the duodenum or pylorus from adhering to a suture gall bladder area, and other

Another type of case which is very apt to give a most tantalizing aftermath is found in that thick, heavy, pendulous, superfluous fat abdominal wall where because of its weight a constant pressure is exerted upon the abdominal wound closure suture line and the intestinal coils which are very apt to adhere to this closure line. Here the Cargile membrane plays a most important part when used to cover over the intra-abdominal contents just below the closure line of sutures. A double layer of Cargile membrane placed along this area will prevent any anterior wall adhesion of the intra-abdominal contents and give a most satisfactory outcome in these overweight cases.

At times one will find it quite impossible not to have raw areas of a more or less extensive nature even in those clean, intra-abdominal cases. Especially is this true where a very extensive resection of any part was to be accomplished in a very thin individual. Here we do not have any alternative as there is practically no fat to use for at least partially covering over these raw surfaces. Next to Cargile membrane and perhaps first in some instances, fat is our best friend and ally for this purpose. However we must always consider the fact that fat from any intra-abdominal region is already anatomically and normally basally attached to some

intra-abdominal organ or organs and thus, even if advantageously used, will always have the possibility of partial absorption and later contraction, producing that drag and weighty pain so frequently complained of in these postoperative adhesion cases. The use of Cargile membrane eliminates this possibility.

TECHNIC IN ITS USE

The application of sheets of Cargile membrane requires the adherence to certain fundamental principles. Two things are absolutely necessary: an operating-room instrument nurse who has been carefully trained in the handling of this membrane from its release from the envelope to the delivery to the operating field, and an assistant who fully cooperates and understands the instrumental handling of this membrane and its application as well as does the operator. These two fundamentals are absolutely essential for the successful application of the Cargile membrane in proper position with a guaranteed sterility. Every aseptic precaution must be executed to the last degree by the instrument nurse. There is one other thing: Cargile membrane should never be moistened the least particle prior to its application.

In handling Cargile membrane we have found that smooth tissue forceps with a very fine grasping bill serves best. The assistant with his forceps grasps one corner and the operator with his forceps grasps the direct-line opposite corner. The field is widely retracted and the contents fully exposed in proper positions. The grasped, taut edge is applied first and released, and the two direct-line opposite corners of the Cargile sheet are picked up in the forceps and the membrane sheet slowly bound over the raw surface or about the suture line. This is a very important point in its application and if cooperatively carried out will permit of a smooth, unwrinkled application of the membrane. The warm,

moist surface of the part to be covered will very greedily adhere to the membrane, thus covering it over and fully protecting it.

A great deal of patience is required in carrying out this technic which in itself is simple enough if these few rules are followed. At times, especially when a very freely movable wall comes adherent to the area covered, a second layer of this membrane placed directly over the first one will further enhance its usefulness.

Of course, it is understood that any surface must be very carefully sponged free of blood, blood clots or serum, prior to the application of Cargile membrane. Following its application all packed-off abdominal contents or retracted structures are very carefully released and permitted to very slowly and under guidance assume their normal positions. This part of the procedure requires very painstaking movements.

Once the Cargile membrane has been properly and smoothly coapted over the area or about this part, it is pretty apt to maintain its position quite firmly. The closure of the wound is then accomplished and dressed as usual.

One additional precaution, which it is fairly reasonable to observe in all cases, seems worthy of note especially in intestinal surgery: that is, splint the bowel with some form of hypodermic injection for the first twelve to twenty-four hours. By the first six hours the Cargile membrane has become quite a firm part of the surface upon which it has been placed and a little extra time allowed prevents any dislodgment by hyperperistalsis.

Cargile membrane therefore has a wide field of usefulness with a most satisfactory ending in so far as postoperative adhesions are concerned. For ourselves we have learned to believe in it greatly and we use it very extensively in this way, thus very largely eliminating those signs and symptoms previously seen as the result of postoperative adhesions.

SCARLET FEVER

FOLLOWING ABDOMINAL OPERATIONS*

J. P. GREENHILL, M.D., F.A.C.S.

CHICAGO, ILL.

SCARLET fever which follows an operation, a wound or a burn is spoken of as surgical scarlet fever. This condition is not uncommon and a large number of such cases have been reported in the literature. However, it is surprising how few are the case reports of surgical scarlet fever which follow abdominal operations.

The first description of a scarlatiniform eruption occurring after operation was recorded by Civiale¹ in 1858. In the same year Sée² reported a case where a generalized eruption resembling scarlet fever developed after an operation. However, neither of these authors believed he was dealing with scarlet fever. The credit for reporting the first case of surgical scarlet fever is generally given to Sir James Paget³ who in 1864 gave a clinical lecture on surgical scarlet fever following operation. His first case occurred in a boy who had a stone removed from the bladder:

The boy, lately operated on for stone had scarlatina . . . Two days later it began to fade and in a few days had disappeared . . . All went on well for a month, the wound was nearly healed when he had severe pain in passing urine and evacuated with it a considerable quantity of blood from the kidneys . . . Two days after this, he had sore throat, then an eruption like scarlet fever again appeared. It continued for three days and was succeeded by desquamation. The urine in about ten days had gradually regained its natural condition . . .

If I had never seen a case similar to this, I should have hesitated to call it scarlatina; for the symptoms of the first attack were very incomplete and those of the second were unusual and disorderly. But I believe the case was really one of scarlatina modified by the circumstances in which it occurred . . .

About this time last year when scarlatina was very prevalent, I saw six cases after operations in private practice. I have notes

of four more that occurred either before or since and I have heard of many more. By some these cases may be supposed to have been only casual coincidences of scarlatina with surgical diseases; but, if they were so, we ought to find a proportionate number of cases among surgical patients not operated on. But this does not happen. In private practice, I do not remember to have seen scarlatina supervene in any surgical cases except those in which operations had been performed; and, in hospital practice, I doubt whether it is much more frequent among all the other patients taken together than it is in those who have been operated on. I cannot, therefore, doubt that there is something in the consequences of surgical operations which makes the patients peculiarly susceptible of the influence of the scarlatina poison. And, together with this susceptibility, we may observe that the disease undergoes in them certain modifications, especially in the period of incubation, which is much shortened. In all the ten cases I have noted, the eruption appeared within a week after the operation . . . Other deviations from the typical course of scarlatina were, that in some of the cases the eruption came out over the whole surface at once, and on the limbs more fully than on the face and chest; in some, there was no sore-throat; in others no desquamation.

The cases are not numerous enough to determine the import of these variable deviations from the type of scarlatina; but that in which all of them, whether complete or incomplete in other characters, agreed, namely, the very early period after the operation at which the rash appeared, deserves particular notice. It adds to the evidence, that the appearance of scarlatina is in some way connected with the early consequences of operations. If it were not so, and if patients after operations had only the same liability as others, there would be no reason why the eruption should appear early, rather than late, after the operation; but, as far as I have seen, it always appears early—always within the first week.

Two explanations may be offered of this

* Submitted for publication December 31, 1929.

fact. Either the condition induced in a patient by a surgical operation is one that gives a peculiar liability to the reception of an epidemic or contagious morbid poison, and any one of these, being imbibed immediately after the operation, produces its specific effect in much less than the usual period of incubation; or else those who suffer with scarlatina within a few days after operations had previously imbibed the poison, but would not have manifested its effects so soon, if at all, unless their health had been exhausted or disturbed. The second of these explanations appears rather the more probable; for it is in accordance with what has been observed when many persons have been exposed to the contagion of fever, and some have been afterwards exhausted by fatigue or otherwise. These have had fever; while those who rested after exposure have escaped it.

But, whatever explanation may be given, the fact of peculiar liability to scarlatina after operations seem certain, and may be important in relation both to the pathology of the disease and to the risks of surgery. In one of the cases which I have seen, it was fatal; in another, it was followed by fatal pyaemia; and I think it not improbable that, in some cases, deaths occurring with obscure symptoms, within two or three days after operations, have been due to the scarlet fever poison hindered, in some way, from its usual progress.

Immediately following the publication of Paget's lecture a number of cases of surgical scarlet fever were reported.

In 1881 at the International Medical Congress in London, Riedinger⁴ and Marsh⁵ read papers on surgical scarlet fever. In 1882 Batut⁶ wrote a thesis on this subject and his belief was that there was no relationship between trauma and scarlet fever but that the association was simply a coincidence.

In 1887 Hoffa⁷ wrote a critical review of the literature on surgical scarlet fever. He rejected most of the reported cases and accepted only those cases in which the eruption began in the wound. This author divided the eruptions which follow surgical operations into four types: (1) a vasomotor disturbance due to irritation

of the sensory nerves and evidenced by a transient urticaria or erythema; (2) a toxic erythema due to absorption of aseptic pyrogenous material from the traumatized area; (3) an infectious rash which occasionally occurs in septicemia or pyemia and is due to minute emboli composed of bacteria which lodge in the capillaries, and (4) true scarlet fever with the usual symptoms and complications, the microorganisms having entered by way of the wound and the eruption often beginning at the edges of the wound.

In 1902 de Bovis⁸ exhaustively reviewed the literature and collected 150 cases but in his analysis he made use of only 100 cases because the others had insufficient clinical data. But even in the selection of these 100 cases, he was very liberal. He believed there were five points of difference between surgical and medical scarlet fever, as follows: In surgical scarlet fever a larger proportion of adults are attacked, there is slight or even absent angina, a short period of incubation, the eruption starts in or near the wound and desquamation occurs early or may be absent.

The last extensive review of the subject was made by Hamilton⁹ in 1904. Her analysis covered 174 cases collected from the literature and to these she added 10 new cases. The whole subject was thoroughly discussed and the literature carefully analyzed in her paper. She stated that de Bovis' five points of divergence of surgical from medical scarlet fever are points in the diagnosis of erythema scarlatiniforme. The latter eruption when caused by toxemia or septicemia may come on a few hours after an operation of any kind or at any time in a long-continued suppurative disease. Hamilton points out that it is difficult to find two authorities who entirely agree on the cardinal symptoms which must be present to make a diagnosis of scarlet fever. The rapid onset of the symptoms, the early appearance of a characteristic rash, first on the chest and neck, then rapidly be-

coming general, the angina, the swelling of the lymphatic glands, the nephritis and the desquamation make up the typical picture of scarlet fever. But there are real cases of scarlet fever without fever, rash, angina, swelling of the glands, or nephritis. Desquamation, which is a late symptom, may be scanty or atypical, and even if it is characteristic it proves very little, because it follows other eruptive diseases also, such as erysipelas and erythema scarlatiniforme. Because of the great variability in the symptomatology of scarlet fever it may be difficult to differentiate scarlet fever from other diseases. The most common afflictions which give rise to confusion are sepsis and pyemia, erysipelas, the rash occasionally seen in diphtheria, especially in case of mixed infection with pus organisms, rashes due to poisoning by drugs and erythema scarlatiniforme. The latter disease is "a febrile affection occurring idiopathically or in association with septicemia, pyemia, autotoxemia, or drug or food poisoning, its most distinguishing features being the scarlatina-like eruption, the non-contagiousness and the tendency to recurrence."

According to Hamilton it seems justifiable to rule out as unproved all those cases in the literature of surgical scarlet fever in which the presence of toxemia or septicemia was highly probable and in which the symptoms deviated from those of typical scarlet fever but not from the symptoms of toxemia or septicemia. In the cases where the disease was undoubtedly scarlatina, Hamilton maintains "there is no convincing evidence that the relation between the wound and the scarlet fever was anything more than one of coincidence." "There is as yet no convincing proof in the literature that surgical scarlet fever is anything more than scarlet fever in the wounded."

In an article on Scarlet Fever in *Abt's "Pediatrics,"* Weaver¹⁰ mentions that there were 27 cases of surgical scarlet fever among 2595 cases of scarlet fever in the Durand Hospital (Chicago). He

is of the opinion it has not definitely been shown that scarlet fever is more readily contracted by persons with wounds than others. The virus of scarlet fever may be introduced into the body through wounds and it would be proper to limit the term surgical scarlet fever to such cases. Weaver²⁷ believes that in some cases in which the infection enters through wounds, there seems to be quite a long period before general infection occurs and clinical scarlet fever develops.

REPORTED CASES FOLLOWING ABDOMINAL OPERATION

In spite of the extensive literature which has accumulated since Paget's first report in 1864 I have been able to collect from the literature only 32 cases of scarlet fever which followed abdominal operations. Certainly many more cases have occurred and have been recognized but they have not been reported. On the other hand, a few cases, as for example the first one listed below, cannot definitely be considered as cases of surgical scarlet fever because the clinical data are insufficient. They are, however, included because the authors may have had good reasons for reporting these cases as surgical scarlet fever. Brief abstracts of the cases described in the literature follow:

1. Paley and Goodhart,¹¹ 1879. A boy, aged four, was operated upon for a hernia on July 2, 1875. On July 25 his temperature rose to 101°F., he was drowsy, had a furred tongue, tonsillitis, swelling of the submaxillary glands and a uniform red rash on the legs. The wound looked clean and the child was much better on the twenty-seventh. There was no note concerning desquamation or albuminuria. Seven months later the child had an attack of measles.

2. P. Bollici,¹² 1890. On October 6, 1888 a bilateral salpingo-oophorectomy was performed. The patient had a normal temperature until the sixth day when high fever was noted and she had abdominal pain, headache, anorexia and burning sensation in the wound. However, the latter looked clean. An erythema was observed on the inner surface of the leg

and over the left lower quadrant of the abdomen. On the eighth day, the limbs and face were involved and blisters formed. The temperature decreased and by the sixth day after the appearance of the eruption, desquamation was progressing rapidly. It was found necessary to drain the lower angle of the wound.

3. Salomoni,¹³ 1893. A Bassini operation was performed for left-sided inguinal hernia and on the morning following the operation an eruption was found around the incision. Later it was localized over the lower left quadrant of the abdomen and the upper part of the thigh. During the following days it spread. High temperature persisted for three days and there was oozing from the wound. Recovery was complete after eighteen days.

4. McGraw,¹⁴ 1895. A boy, aged fifteen, who had had scarlet fever when he was eight years of age, was operated upon for gangrenous appendicitis with abscess formation. The appendix was removed and a rubber drain left in the abdomen. Five days after operation the patient had a chill and fever. The following day the temperature was 102°F., the throat was sore and there was a generalized scarlet rash. The tongue developed the regular strawberry appearance seen in scarlet fever. The boy vomited considerably but the abdomen was flat and free from tenderness. The wound was clean. Fever persisted until death. At autopsy the cause of death was found to be volvulus.

5. Moeller,¹⁵ 1902. A nine-year-old girl was operated upon for bilateral inguinal hernia. Because the child was anemic, and had a persistent cough, each hernia was operated upon separately. The first operation was performed on October 21, 1901 and the wound healed by first intention. The second operation was done on November 6. On the evening of the third day following the latter operation, high fever was observed, the child was stuporous and her body was scarlet red. Tonsillitis was found the next day and a scarlatiniform eruption appeared on the chest. The tongue assumed the raspberry aspect characteristic of scarlet fever and the eruption spread all over the body. On the seventeenth day desquamation occurred. Both wounds remained clean but on one side the edges separated.

6. Martin,¹⁶ 1903. A woman, aged thirty-eight, who had had scarlet fever at the age of fourteen, had an appendectomy performed

on April 3, 1901. On April 5 the pharynx, mouth, tonsils and tongue showed a raspberry color, the patient had frequent fits of coughing and she had high fever. An exanthem appeared first on the neck and soon covered the entire body. On April 8, pus was obtained from the wound and on the tenth desquamation commenced. A large amount of albumin was found in the urine. By April 20 the desquamation was complete. The wound was not entirely healed until two months after operation.

7. Gerasimovich,¹⁷ 1903. On a six-year-old child an operation for right inguinal hernia was performed on February 23, 1902. The next day fever developed and this increased gradually. On the twenty-sixth, the wound was found to be reddened, infiltrated and slightly purulent and on the twenty-seventh a pale pink eruption appeared. The pharynx was hyperemic and the tongue furred. On March 1 the characteristic tongue of scarlet fever was observed and the pharynx was red. The patient was transferred to the scarlet fever ward. Desquamation began March 9 and on the fifteenth there was an inflammation of the middle ear which subsequently cleared up. Staphylococci were recovered from the blisters around the wound, streptococci from the pus in the wound and diplococci and streptococci from the pharynx.

8. Gerasimovich, 1903. A child, aged one year and eight months, was operated upon for inguinal hernia on April 25, 1902. Fever developed four days after operation and a pale pink scarlet fever eruption appeared on the body. On May 1 the wound was found to be suppurating. The following day the characteristic tongue of scarlet fever was noted and there was high fever. The patient was transferred to the scarlet fever ward. On May 9 desquamation commenced. The wound closed after having drained a long time. Diplococci and streptococci were recovered from the pharynx and saprophytic bacteria from the wound.

9. Nicolotti,¹⁸ 1904. A herniotomy was performed on a boy nine years old and on the following morning there was slight fever, tachycardia, a coated tongue and a reddened throat. The next day an eruption was seen all over the lower part of the abdomen and around the wound. The eruption spread to the thorax and back. On the sixth day desquamation began. The wound healed per primam.

10. Bernard,¹⁹ 1906. An operation for the cure of an inguinal hernia was performed

on a six-year-old child. The herniated mass consisted only of the appendix which was adherent to the sac of the hernia. One week after operation the patient developed high fever and a pronounced case of scarlet fever manifested itself. The wound was probed and thick pus escaped under pressure. It was ascertained that there were a number of cases of scarlet fever at the school which this child attended.

11. Davidovitsch,²⁰ 1908. On September 25, 1894 a twenty-six-year-old woman had a ventrofixation of the uterus. On September 28 there was fever and dysphagia. Eight days after operation the wound was found to be slightly infected. The skin was red, the tongue presented the characteristic appearance seen in scarlet fever and there was slight conjunctivitis. Desquamation took place and the patient left the hospital October 2.

12. Davidovitsch,²⁰ 1908. A thirty-year-old patient was operated upon for bilateral hernia on February 18, 1902. Two days later a scarlatinal rash was observed over the entire body. The wound healed by primary intention. Desquamation occurred and on May 6 the patient left the hospital.

13. Davidovitsch,²⁰ 1908. A woman, aged forty-five, had a ventrofixation performed the latter part of February, 1902. Shortly after operation there was high fever, dysphagia and a diffuse scarlatinal rash all over the body. The tongue and throat were coated. The urine contained albumin from March 15 to 31. The patient was discharged May 20.

14. Davidovitsch,²⁰ 1908. A patient, aged twenty years, was operated upon for appendicitis April 10, 1905. On April 15 she had severe pain in the throat, headache and a rash over the entire body. The face was dark red, the right tonsil swollen and coated and the cervical glands swollen. Desquamation occurred and the patient was discharged June 13.

15. Davidovitsch,²⁰ 1908. A woman, aged thirty-six, had an Alexander-Adams operation on July 8, 1905. On the eighth postoperative day there was fever, difficulty in swallowing and a scarlatinal erythema over the entire body. The face and cheeks were very red; the tongue was reddened at the edges and the papillae were raised. The throat was red and swollen but not coated. There was albumin in the urine for five days. Desquamation occurred in large pieces. The wound healed normally and the patient was discharged August 28.

16. Davidovitsch,²⁰ 1908. A forty-three-year-old woman had an anterior and posterior colporrhaphy and an Alexander-Adams operation on July 15, 1905. On July 20 fever and a scarlatinal rash over the entire body were noted. The face and tongue were red, and the throat was likewise red and swollen but not coated. There was slight suppuration of the wound. Desquamation occurred and the patient was discharged on August 25.

17. Davidovitsch,²⁰ 1908. On September 25, 1905, a laparotomy was performed for myomata of the uterus. Three days later there was an elevation of temperature and on the seventh day a scarlatinal exanthem was observed on the chest. The tongue was coated, the tonsils were normal, and there were no glandular swellings. The wound was found to be infected. The fever lasted five days. Desquamation occurred and the patient left the hospital on November 16.

18. Davidovitsch,²⁰ 1908. A girl, aged sixteen years, was admitted to the hospital March 27, 1906. She had had two operations for hematosalpinx, the first three weeks before admission, and the second two weeks later. Immediately after the latter operation, there was high fever, difficulty in swallowing and a scarlatinal rash. The tongue and throat were fiery red and there was albumin in the urine. Desquamation occurred and the patient was discharged on May 14.

19. Davidovitsch,²⁰ 1908. A girl, aged eleven years, had a herniotomy on April 8, 1907. Four days later fever and a rash were present and the patient complained of a sore throat and headache. The tonsils were enlarged and red, and the submaxillary glands were swollen. Desquamation took place. The wound healed per primam and the patient left the hospital May 10.

20. Roberts,²¹ 1915. A twenty-seven-year-old woman had her appendix removed and made an uneventful recovery until the ninth day postoperative when there was a rise in temperature and a sore throat developed. Two days later an eruption appeared over the neck, chest, arms and back. A diagnosis of scarlet fever was made and the patient was sent to the scarlet fever pavilion of a contagious hospital. She made a complete recovery.

21. Port,²² 1922. A boy aged two and one-half years was admitted to the hospital on July 30, 1918. Eight days previously he had been operated upon for an inguinal hernia.

At the time of admission the temperature was 104°F. and there was a typical scarlet fever exanthem over the entire body. On August 14 there was extensive desquamation. On August 25 the child, although still desquamating, was discharged upon request of the parents. The wound healed by first intention.

22. Port, 1922.²² A twenty-seven-year-old man had an appendectomy September 27, 1927. On October 3, he developed high fever and headache. The next day there was pronounced redness on the neck, limbs and face, and on the following day angina developed. A glass drain was inserted into the wound. On October 16 there was extensive desquamation. By October 25 the wound was closed but desquamation continued until November 12.

23. Port, 1922.²² From a patient, aged nineteen years, the appendix and an ovarian cyst were removed on April 16, 1917. The next day she developed signs and symptoms of scarlet fever and was transferred to the contagious ward. On April 20 the scarlatiniform rash extended all over the body. On May 15 there was extensive desquamation. The patient was discharged on June 2 after the wound had been completely closed for one week.

24. Port,²² 1922. A two-year-old girl was operated upon for a hernia February 14, 1917. The following day she developed fever and a light red exanthem on the neck and limbs. The throat was red. On February 28 the wound was found to contain pus. On March 11 there was desquamation. The patient was discharged April 4.

25. Günther,²³ 1924. A fifteen-year-old boy was operated upon for appendicitis and diffuse peritonitis. Drainage was instituted. Four days after operation there was high fever and nausea. The following day a scarlet fever eruption appeared on both flanks and soon spread over the entire body. Angina also appeared and desquamation began fourteen days after operation. The wound healed rapidly.

26. Floris,²⁴ 1927. A woman, aged thirty-two years, had a subtotal hysterectomy and bilateral salpingo-oophorectomy for suppurating fibroids. The operation was performed under lumbar anesthesia on September 11, 1926. On the fourth day after operation a red eruption, scarlatiniform in character, appeared on the neck, thorax and back. There was pyrexia and tachycardia and the throat was reddened.

Signs of hyperthyroidism were evident. The following day, the eruption became generalized. Desquamation followed but the signs of hyperthyroidism persisted. The patient left the hospital on October 25, but returned the following January with symptoms of malignancy in the lungs. She died February 1. Subsequent careful examination of the fibroids removed at the operation revealed sarcomatous degeneration.

27. Rivaroli,²⁵ 1927. A man was operated upon October 1, 1926 for suppurating hydated cyst of the liver. He developed scarlet fever on the third day after operation.

28. Rivaroli,²⁵ 1927. Another patient was operated upon for a hydated cyst of the liver on December 31, 1926. Symptoms of scarlet fever appeared on January 3, 1927.

29. Rivaroli,²⁵ 1927. A male patient was operated upon for an ectopic testicle on June 10 and he developed scarlet fever on June 14.

30. Rivaroli,²⁵ 1927. A patient had an appendectomy on July 6, 1926, and began to show signs of scarlet fever on July 8.

31. Rivaroli,²³ 1927. A young girl had her appendix removed and two days later a scarlatiniform eruption appeared accompanied by fever. Desquamation occurred shortly afterward.

32. Winter,²⁶ 1929. This case was mentioned in an article which Winter wrote on cesarean section based upon information received by means of questionnaires. I am indebted to Professor Stoeckel whose patient this was for the history of the case. A primipara, aged twenty-six, was delivered by means of a cesarean section on February 28, 1928, because of toxemia and abruptio placentae. On March 2, there was fever and a sore throat. Cultures from the throat showed hemolytic streptococci. There was marked edema and eruption all over the body, circumoral pallor and a raspberry tongue. The wound was clean. A diagnosis of scarlet fever was made and the patient transferred to the isolation pavilion where the diagnosis was confirmed. Scarlet fever serum was given and this was followed by typical eclamptic convulsions. The rash became more pronounced and after more convulsions the patient collapsed and died. Autopsy revealed exudative peritonitis in the presence of a well-healed operative wound, fatty degeneration of the kidneys with multiple hemorrhages, fatty degeneration of the liver with hemorrhages and a soft spleen.

UNREPORTED CASES

To these 32 cases reported in the literature, some of which probably were not true cases of scarlet fever, I should like to add the following case reports. The first case is the only one I have personally encountered.

CASE I. Miss P. P., No. 1,071,474, age twenty-two, was admitted to the Cook County Hospital on July 11, 1928 complaining of pain in the lower abdomen and leucorrhea which had been present for three years. The pain had begun suddenly three years before admission and had recurred periodically about every four weeks. The attacks which were severe usually lasted about seven to ten days and subsided after rest in bed and ice bags placed on the lower abdomen. During this time a profuse leucorrheal discharge was present and dysmenorrhea also was a prominent symptom. The last menstrual period had begun July 6, 1928 and, for the first time, the flow was excessive and lasted nine days.

The patient had had a number of childhood diseases but she was not certain she had had scarlet fever. Her tonsils had been removed four years before admission. The menses began at twelve years of age, recurred every twenty-five days and generally lasted three days without pain until the present illness began. The general physical examination revealed no abnormalities. There was definite tenderness in both iliac fossae and slight rigidity in both lower quadrants but no masses were felt. Vaginal examination revealed the following: There was a nulliparous outlet, a long, hard and irregular cervix and a corpus uteri of normal size, hard, anteflexed and movable. In both fornices were tender, cystic and adherent masses. The one on the left was about 7 cm. in diameter and the one on the right was much smaller. The diagnosis was pelvic inflammatory disease with a tubo-ovarian abscess on the left side.

An operation was performed on July 20 and I removed a tubo-ovarian abscess from the left side and a pyosalpinx from the right. The patient did well the day of the operation and the following day.

On the third day the temperature rose to 101°F. but the patient insisted she felt well. On the fourth day there developed a generalized, red, maculopapular eruption with an

underlying erythema. The rash was most prominent on the flexor surfaces of the extremities. The tongue was red, glossy and strawberry-like. A diagnosis of scarlet fever was made and the patient was transferred to the Contagious Disease Hospital. At the latter hospital, examination showed that the maculopapular rash involved the axillae, the breasts and the flexor surfaces of the extremities with definite linear markings in the cubital regions of the arms. There was a slight eruption over the upper abdomen and back, but none on the face and neck. The tongue was strawberry and almost raspberry in appearance. The papillae were enlarged, hence the disease was in about the fourth-day stage, but the rash had the appearance of an earlier stage. There was slight congestion of the pharynx. A diagnosis of surgical scarlet fever was made. Two days after admission to the Contagious Disease Hospital the rash was fading rapidly but the tongue was still typical of scarlet fever. The skin sutures were removed July 28 and a small abscess was found in the region of the lowest stitch. Otherwise the wound had healed perfectly. On July 31, there was desquamation on the face, neck, abdomen and extremities. Following this, the convalescence was fairly good and the patient left the hospital on August 15.

CASE II. (I am indebted to Dr. K. Speed for the following case report.) L. A., No. 1055-884, aged six, was admitted to the Cook County Hospital, March 27, 1928 because of a swelling in the left half of the scrotum. The past history was negative and the general examination revealed no abnormalities. In the left half of the scrotum was a swelling which was soft and the size of a walnut. The swelling was reducible and gave a distinct impulse on coughing. The point of reduction lay medial to but was separate from the internal abdominal ring. A diagnosis of left direct inguinal hernia was made and on April 4, Dr. K. Speed operated on the boy. On the third day following operation the temperature rose to 103°F. and there was much tenderness and induration around the herniotomy wound. The next day the temperature was the same, the pulse was 128 and the respirations 28 per minute. A punctate erythematous rash was noticed, involving the back of the neck, arms and chest. No Koplik spots were present and the tongue appeared normal. The throat

was negative and the wound looked clean. The white blood count was 29,200. On April 9, the temperature was 101°F., the tongue showed prominent papillae and the throat was moderately congested. The wound was infected and when opened permitted a bloody purulent discharge to escape.

The patient was transferred to the Contagious Disease Hospital with a diagnosis of scarlet fever. At the latter hospital examination showed a punctate erythema over the entire body and extremities. The face was slightly red and there was circumoral pallor. The rash disappeared on pressure. The throat was reddened but the tongue was not involved. A definite diagnosis of scarlet fever was not made until the following day. On April 17 desquamation was taking place, especially on the hands and feet. On May 4, quarantine was lifted and on May 6 the boy was transferred to the children's surgery ward where the infected wound was treated. The boy was discharged on May 25 at which time the wound had practically healed entirely.

CASE III. (I am indebted to Dr. A. L. Hoyne for the following two case reports.) R. F., No. 1120560, aged eighteen, was admitted to the Cook County Hospital on June 10, 1929 because of severe pain in the right lower quadrant and vomiting. The temperature was 99.4°F., and the pulse 104 per minute. The white blood count was 18,000 and the urine negative. There was tenderness and rigidity in the right lower quadrant and a diagnosis of subacute appendicitis was made. The condition subsided and the patient was operated upon on June 22 by Dr. Johnson. The pathological diagnosis was subacute appendicitis. On the evening of the second day the temperature rose to 103°F., and the pulse was 114 per minute. The pharynx was injected. The next day the temperature was the same, the pulse rose to 140 and the pharynx remained injected. The wound was in good condition. A diagnosis of acute pharyngitis was made but the patient was isolated because there was a suspicion the condition might be scarlet fever. The patient's mother said the patient had had scarlet fever in childhood. On the evening of the third day after operation, the temperature rose to 105°F., The next day Dr. Hoyne saw the patient and made a diagnosis of scarlet fever. The patient was transferred to the Contagious Disease Hospital immedi-

ately. At this time a strawberry tongue was present. Early the following morning symptoms of collapse appeared and the patient died shortly afterwards. An autopsy was not obtained.

CASE IV. L. H., a white woman eighteen years of age, was admitted to the Municipal Contagious Disease Hospital with a typical attack of scarlet fever on June 24, 1929. She had been operated upon for pyosalpinx on June 14 and developed scarlet fever six days later. On admission pus was being discharged from the abdominal incision. The patient had multiple arthritis of a mild degree as a complication of her scarlet fever. She made a complete recovery and was discharged on August 1.

In addition to these unreported cases I have received from Dr. George H. Weaver the following 4 brief case reports of scarlet fever following abdominal operation. These cases were observed at the Durand Hospital during a period of fifteen years from 1913 to 1927 and occurred among 3,979 cases of scarlet fever. During the same period there were 52 cases of surgical scarlet fever in the hospital, but only the 4 described below followed abdominal operations:

CASE V. A child, No. 2623, aged five, had an operation for appendicitis on January 1, 1918. The abdominal wound suppurated and beginning January 20, typical scarlet fever developed.

CASE VI. Patient No. 4241, aged nineteen had a bilateral salpingectomy performed about one month before admission on March 15, 1920. On entrance to the hospital the wound was open and suppurating. From the pus in the wound numerous hemolyzing streptococci were cultured and typical scarlet fever was present. The scarlet fever began about three weeks after the operation.

CASE VII. Patient No. 6739, aged thirty-six, had her fallopian tubes removed March 14, 1923. On March 18 she had chills, fever and a sore throat. On March 21, a scarlet fever eruption appeared and the wound was slightly infected.

CASE VIII. Patient No. 9321, aged six, had a herniotomy performed on April 16, 1926. On April 20 typical scarlet fever developed and

hemolyzing streptococci were cultured from the infected wound.

SUMMARY

The literature on surgical scarlet fever was reviewed and all the cases following abdominal operation were abstracted. To the 32 cases reported I have added 8 unreported cases, all of which occurred in Chicago. Many other cases have certainly been encountered, not only in Chicago

but elsewhere, but they have not been reported in the literature. Surgical scarlet fever does not differ from the non-surgical type and the symptomatology and treatment are identical. It may not be amiss to emphasize that surgeons who attend cases of scarlet fever should be especially careful in their asepsis when operating. During epidemics of scarlet fever, only those operations should be performed which are absolutely imperative.

IMMEDIATE CAUSES OF DEATH FOLLOWING OPERATIONS ON GALL BLADDER & DUCTS*

E. MACD. STANTON, M.D. F.A.C.S.

SCHENECTADY, N. Y.

THE study which forms the basis of this thesis was first suggested to the writer when at a staff surgical conference which he attended the question was asked, "What are the chief causes of death following gall bladder operations?" From the discussion which followed it was quite evident that among the several surgeons present no one had any really satisfactory knowledge of the subject. A subsequent review of the literature revealed the fact that notwithstanding the rather abundant literature dealing with the mortality rates associated with gall bladder surgery, there is a decided paucity of systematized data concerning the relative frequency of the various causes immediately responsible for the mortality following operations on the biliary tract. In order to get the desired information on this subject, the writer has collected from the literature the causes of death as given in 400 fatal cases. Also, in addition to the above, and for the purpose of more detailed comparative studies, he has reviewed the hospital charts and other available data pertaining to 100 postoperative gall bladder deaths collected from his own case histories, from the records of the Ellis Hospital and from the records of fatal cases furnished by a number of his surgeon friends.

Table 1 gives a summary of the causes of death as collected from the literature and from the personally studied case histories, the combined figures comprising a total of 500 fatal cases.

The term, cause of death, to a large extent represents a clinical opinion and even with most detailed data including autopsy findings opinions may differ in the individual case as to the actual cause of death. Nevertheless, when a fairly

large series of cases is studied, it is found that a considerable proportion of the

* Presented before The American Association of Obstetricians, Gynecologists and Abdominal Surgeons, Memphis, Tenn., Sept. 1929

individual cases falls into sharply defined groups which can be determined with far more certainty than the detached individual case. I believe that the series here reported does give a reasonably accurate picture of the causes of death encountered by a number of surgeons in the course of approximately 10,000 gall bladder operations.

The hazards of gall bladder surgery naturally fall into several more or less sharply defined categories, as for instance, the dangers incident to the operation itself, the dangers due primarily to the disease process itself and the dangers more or less associated with the age and general condition of the patients who suffer from gall bladder disease.

Operative shock and hemorrhage account for a total of 57 deaths, or 11 per cent of all of the operative fatalities. From the literature data, it would seem that operative shock and hemorrhage are about equally responsible, there being 25 cases classed as shock and 23 as hemorrhage. However, most of the 9 cases from the personally studied charts now listed under hemorrhage were charted as deaths due to shock. In studying the operation reports and charts of these 9 cases, it is perfectly clear that hemorrhage was the primary cause for nearly all of these immediate operative disasters. A clamp or ligature slipped, or a vessel was torn, and then the trouble began. These operative hemorrhage deaths represent 9 per cent of the total mortality of my series and the shock and hemorrhage cases account for 11 per cent of the deaths collected from the literature and yet, they represent only a fraction of 1 per cent of the total cases operated. The problem of the control of hemorrhage during operation is a purely technical one. Careful, accurate technic with the application of sound judgment in the presence of difficulties can certainly reduce the incidence of hemorrhage and shock to a point where it does not represent anything like $\frac{1}{10}$ of the total hazard of gall bladder operations.

Pulmonary embolus accounts for 33 deaths, or 6.6 per cent of the total. In the writer's series only 2 per cent of the deaths were ascribed to pulmonary embolism, whereas in the group collected from the literature nearly 8 per cent are listed as due to this cause. When going over the literature, I was inclined to feel that some of the surgeons reporting cases were perhaps partial to pulmonary embolus as a cause of death. It seems probable that the 6.6 per cent as represented by the combined figures may represent approximately the truth. Wilson¹ records only 9 deaths from pulmonary embolism in 4597 operations on the gall bladder.

Only 3 deaths are listed as due to fat embolism. The writer is, however, inclined to believe that fat embolism may have been a contributing cause of some of the deaths listed under other causes.

Along with the other causes of death associated directly with the operation itself, 20 deaths are listed under the term, "high temperature rapid deaths." In the writer's series collected directly from the clinical records, this is the most frequent terminal picture encountered. In this series, it is represented by a rather sharply defined group of 15 cases which can be assigned to no other cause or causes. It seems probable that at least 3 or 4 other deaths occurring in this personally studied series could properly be placed in this group but, because in the recorded histories other causes have been definitely assigned by the attending surgeons, they have not been listed as high temperature rapid deaths.

The charts of the 15 cases included in this group present a striking and, I believe, a sharply defined picture. They are characterized chiefly by a rapid, steady rise in temperature. Before death, temperature readings of 105° to 106° or even higher are not uncommon. The temperature rise usually begins within six to twelve hours after the operation. With the temperature once started on its upward trend, there

¹ WILSON. Fatal postoperative embolism. *Ann. Surg.*, 56:811, 1912.

are seldom any remissions and death usually ensues within thirty-six to forty-eight hours. Along with the rapid and extreme rise in temperature these patients present a greatly accelerated, weak pulse, extreme nervousness and, toward the last, rapid shallow respirations. Charts Nos. I to VI show the character of the temperature, pulse and respiration curves encountered in these cases. One other point of interest in connection with these cases is the fact that in not one of the 15 deaths had the surgeon in attendance ventured an opinion as to the cause of death.

The writer knows of no other terminal picture occurring in surgical cases which very closely simulates these high temperature rapid deaths. While individual cases occurring once or twice in several years' work might escape notice, the combined group stands out in a manner which suggests that this type of death may be as closely associated with biliary surgery as is postoperative hyperthyroidism with goiter surgery.

During the past few months, I have discussed the problem of these cases with possibly 25 surgeons, every one of whom can remember similar tragedies in his own practice. No one of them, however, has had any satisfactory explanation to offer as to the cause. Among those who have given special study to gall bladder surgery or who have done experimental work on the gall bladder and liver, no two have agreed on the possible explanations they have suggested. One says, "we believe these particular patients died from absorption of either diseased or chemically altered liver cells or toxic bile." Another experimental investigator suggests that altered cholesterol metabolism may be responsible while still another suggests that injury to the nervous mechanism of the liver may be responsible for these fatalities.

In the literature I have been able to find only one undoubted reference to this type of death. Cave² in 1926 in reporting

35 postoperative gall bladder deaths from the Second Surgical Division, Roosevelt Hospital, under the head of "Immediate Operative Mortality of Unknown Origin" reports 3 of these cases as follows:

There were three cases that died within forty hours with immediate hyperpyrexia one 107.2 degrees, another 106 degrees and the other 107 degrees; hemorrhage, peritonitis, pneumonia, embolism were all ruled out clinically; in all cholecystectomy was the procedure. These were not the acutely inflamed type but simply cases with symptoms of prolonged chronic cholecystitis with calculi in the gall bladder in otherwise healthy women, not jaundiced. In one, a cholecystostomy had been done one year previously. According to the operative notes the procedures were carried through without difficulty, in fact, two noted as being extremely easy. All three were drained, one through the upper angle of the wound, the other through lateral stab wounds with tight closure of the anterior abdominal wound. It seemed that immediately the operation was finished, the temperature began to rise and reached exceedingly high levels with an accompanying rapid pulse rate. Although no mention is made of unusual liver traumatization except in one instance, we believe these particular cases died from absorption of either diseased or chemically altered liver cells or toxic bile. The appearance or consistency of the liver was not noted.

It is a startling and helpless situation to follow to its quick termination one of these catastrophies—the last one of these three here reported occurred in a young healthy vigorous Greek woman of thirty-five with a definite and classical history of diseased gall bladder for a period of over three years without jaundice; heart, lungs, kidneys normal; cholecystography revealed numerous shadows indicative of stones in a slightly enlarged gall bladder. Operation upper right rectus incision and easy and splendid exposure of gall bladder and ducts; the cystic artery and duct fully exposed; comfortably handled and twice transfixed with chronic catgut before being cut across and the third ligation of the duct and artery made by transfixion and tying after removal of the clamp and the gray-walled, stone-filled gall bladder; the excision being easily carried out from below upward. The liver bed from which it was removed was rather broad, however, with only

² CAVE, H. W. Dangers incident to cholecystectomy. *Ann. Surg.*, 84: 371-378, 1926.

moderate oozing; the sulcus sutured over with the stump of the cystic artery and duct securely tucked and sutured into it at its lowermost angle, so dry was the area that it was remarked to be an ideal case for closure without drainage, however, a lateral stab wound to flank, wrapped tube drain to Morrison's pouch and a tight closure of the anterior abdominal wound was done. Immediate precipitous rise of temperature to 106 degrees at the termination which took place in forty hours. Pulse rate rose steadily with temperature curve to 154, no signs of pneumonia clinically or from portable x-ray films, a dressing done the drain loosened and withdrawn a short distance, a slight amount of bile-stained secretion on the dressing. No evidence whatever of hemorrhage.

I have also found two other individual cases reported in the literature. The typical clinical picture is described in each instance without to diagnose the cause of death.

The clinical picture is almost certainly that of an overwhelming toxemia. Because in one of my early cases I found at autopsy a definite acute cholangitis extensively involving the intrahepatic bile ducts, and because within the scope of my observations several of these deaths had occurred following operations performed during or just following acute attacks, I had until quite recently felt reasonably certain that these deaths were due to acute cholangitis. The very direct relationship of the onset of the hyperpyrexia to the operation, I had postulated as being in some way due to the lighting up of an infection as a result of operative manipulations or interference with liver functions. More recently a number of facts have been observed which do not square with the cholangitis hypothesis. In the first place, microscopical examination of the liver as found at autopsy does not always show the expected degree of cholangitis. Also, I have among my charts a recent case of a young man, age twenty-three, who died forty-seven hours after a traumatic rupture of his liver. Hemorrhage from a 2 in. rent in the dome of his liver was the predominating intra-abdominal finding, both at opera-

tion six hours after the injury and at autopsy. Most certainly this young man did not have a cholangitis. Had the same amount of intra-abdominal hemorrhage been the result of an ectopic pregnancy or a ruptured spleen, the clinical picture would have been that of the shock due to the hemorrhage, namely, a rapid pulse with a subnormal or but slightly elevated temperature. In this case of ruptured liver, the temperature began to rise soon after admission and reached 105.6° twenty-two hours after the accident. The clinical picture presented by this traumatic liver death is so strikingly similar to that seen in the high temperature, rapid deaths following gall bladder operations that I am led to suspect very strongly that similar factors are operative in each instance.

What these factors are I am unable to state at the present time. In many respects the high temperature, rapid pulse clinical picture is not totally unlike postoperative hyperthyroidism. Crile has shown a close interrelationship between the thyroid, the adrenals and the liver. The complex relations of the liver to states of shock and to basal metabolism have been studied by many investigators. Nowhere in the literature that I have so far studied, have I come across any data tending to throw much light on the problem presented by the 15 high temperature, rapid deaths found in this series.

It is possible that the blood chemistry observable during the period between operation and death might throw some light on the nature of the condition. We intend making these studies the first time we are unfortunate enough to encounter one of these cases again. The ideal way would be for surgeons interested in the problem to report their findings to a central clearing house for correlation and analysis.

In the series collected from the literature, 3 deaths are listed as due to acute gastric dilatation or pyloric obstruction and 6 deaths as due to intestinal obstruction.

A total of 5 deaths are listed as due to protracted vomiting. Four of these cases

occurred in the series studied by the writer. These 4 deaths presented no other particularly noteworthy features in the terminal picture. The vomiting was of the frequent gulping type not uncommonly encountered after gall bladder operations. Persistent vomiting of this type has long been recognized as one of the common and occasionally dangerous complications following gall bladder operations. In some cases gastric lavage has seemed to give marked relief and if so the condition may be accounted for as being the nature of a temporary pyloric obstruction. Other cases are apparently not influenced by lavage or other therapeutic means. The writer has never been able to account satisfactorily for these cases. It is quite possible, however, that the experimental work of Horrall and others may throw some light on this subject. When bile is injected into the peritoneal cavity of a dog or when it is allowed to flow into the peritoneum through an opening in the gall bladder, persistent vomiting is one of the most constant symptoms of the bile poisoning. In the light of this experimental data, it seems quite possible that absorption of bile either from the free peritoneum or from surfaces in contact with bile-soaked drainage gauze may be the cause of this type of vomiting. When the writer read the reports of Horrall's experiments he resolved that in the future he would be much more careful not only as regards spilling of bile at the time of operation but also as regards the use of drains which might become bile-soaked and serve as reservoirs from which the bile could be absorbed. This whole subject warrants careful clinical study to examine the facts from the viewpoints suggested by the experimental findings.

Among the less common causes of death directly associated with the operation itself, rupture of the incision, anesthesia $N_2O_2 + O_2$, operative injury of the duodenum, serum anaphylaxis following prophylactic injection of rabbit serum to control bleeding and erysipelas of the

abdominal wound account for one death each.

The cases of erysipelas of the abdominal wound is the only instance in the entire series studied in which a surgical infection of the accidental type is given as a cause of death.

In the combined series, peritonitis is credited as the cause of 109 deaths. Thirty-two of these deaths were definitely due to bile peritonitis leaving 77 deaths or 15.4 per cent of the total listed simply as peritonitis. In the writer's series only 4 per cent of the deaths are ascribed to peritonitis other than bile peritonitis while in the cases collected from the literature over 18 per cent of the fatalities are listed simply as due to peritonitis. It seems probable that a considerable proportion of the 73 deaths recorded in the literature as due to peritonitis was due primarily to leakage of bile rather than to intraperitoneal infection. It is only within the last few years that the importance of bile peritonitis distinct from peritonitis of purely infectious origin has been recognized. The peritonitis cases reported in the literature were to a considerable extent grouped in relation to certain types of operative conditions. First, peritonitis as might be expected is frequently associated with operations performed during the acute stage in the severe, fulminating types of cases. Also, it is a frequent cause of death after the more difficult common duct operations and particularly after secondary operations on the ducts. Peritonitis is apparently the chief cause of the deaths occurring in cases in which fistulae between the gall bladder and stomach or intestines are found at operation. Several of the peritonitis deaths followed accidental operative injury of some portion of the intestinal tract.

Thirty-two deaths in the combined series occurred in the presence of spontaneous perforation of the gall bladder or ducts. This condition is considered a relatively rare complication of gall bladder disease but when it does occur it is associ-

ated with a very high operative mortality. In the writer's series, it was responsible for 8 per cent of the total mortality. Gosset, Desplas and Bonnet³ reviewed 111 cases, mostly spontaneous perforation of the gall bladder into the peritoneal cavity in which operation was performed. The mortality was 52.2 per cent. They concluded that frank perforation of the gall bladder is much more serious than perforation of gastric or duodenal ulcer. Meissner⁴ reported 12 cases of rupture of the common duct with 8 deaths and 7 cases of rupture of the hepatic ducts with 5 deaths. Reports from other sources simply confirm the data already quoted.

For a long time it was assumed that the bile itself was relatively harmless and that the lethal symptoms were due to bacterial infection present in the bile. As long ago as 1909 Sellands⁵ showed that 15 c.c. of auto- or hetero-bile injected intraperitoneally into rabbits weighing 1000 gr. caused death in a few hours.

O. H. Horrall has recently reviewed this subject and has added a considerable amount of experimental data and his work has, I believe enabled the clinician to form a clear-cut and accurate concept of the situation. His results may be summarized as follows:

Bile in the peritoneal cavity acts as a true chemical poison. In dogs 5 c.c. or more per k. of body weight causes death within twenty-four hours. Sterilized bile has the same effect as unsterilized bile. Sublethal doses produce toxic effects commensurate with the quantity of bile entering the peritoneal cavity. As regards the treatment of bile peritonitis in the dog, Horrall says:

In a number of dogs the gall bladder was opened and left open as in the early operations, and after varying intervals of time the abdomen was aseptically reopened and the gall bladder closed. Various intervals of time

were set for the closing of the gall bladder, all of which must be within twenty-four hours. At the time the gall bladder was closed, the peritoneal cavity was thoroughly washed out with sodium chloride solution and a quantity of the solution was left in the peritoneal cavity. The dogs in which the second operation was done at eighteen hours all died; one lived at sixteen hours; all lived at twelve hours or less. Apparently, then, the maximum time at which the operation can be done following rupture of the gall bladder is sixteen hours; the preferable time is twelve hours or less.

Seven deaths are listed as due to subdiaphragmatic abscess. This condition is very rarely recognized clinically. On the other hand, it appears to be rather frequently found at autopsy. I believe that it is a more frequent complication of gall bladder operations than the figures would indicate. Its frequency can probably be reduced by careful operative technic and efficient drainage.

One hundred and forty-nine deaths or 30 per cent of the total are listed under causes directly associated with the biliary pathology encountered at operation. The deaths due to perforation of the gall bladder or ducts have already been discussed and are included in the 149 cases. It is impossible to state how many of the other peritonitis deaths were really associated with the disease itself rather than with the operative interference. With these added, it is safe to say that something over one-third of the deaths recorded in the combined series can be traced to the results of the disease itself.

The greatly increased operative risk in the presence of jaundice has always been recognized. In the combined series, 42 deaths are listed as due to cholemia with or without postoperative hemorrhage and 19 as due to hepatic insufficiency following for the most part operations performed in the presence of duct obstruction. Twenty, or approximately half of the deaths listed under cholemia were due to postoperative hemorrhage of the uncontrollable oozing type characteristic of

³ GOSSET, DESPLAS and BONNET. *J. de chir.*, 25: 257, 1925.

⁴ MEISSNER. *Beitr. z. klin. chir.*, 54: 204, 1907.

⁵ SELLANDS, A. W. *J. Exper. Med.*, 11: 786, 1909.

this condition. Since the introduction by Walters of the CaCl_2 method of controlling hemorrhage in the presence of jaundice, we have at our command a means by which a very considerable proportion of the deaths from hemorrhage associated with cholemia can be prevented.

Nineteen deaths are ascribed to cholangitis or liver abscess apparently secondary to cholangitis. It seems probable that cholangitis was an important contributing cause of death in a number of cases listed under other headings.

Common duct stones overlooked at the time of operation were given as the cause of death in 2 cases.

Pyemic processes such as multiple lung abscesses, splenic abscesses and secondary abscesses in other parts of the body account for 16 deaths. This represents only approximately 3 per cent of the total deaths and in some of the cases here included the relation of the pyemic infection to the gall bladder pathology or the operation is rather doubtful. The low incidence of infection per se as a cause of death following gall bladder operations would seem to indicate that infection plays a secondary, rather than a dominant, rôle in the pathological processes associated with this field of surgery.

Acute pancreatitis is listed as the cause of death in 7 cases. The association of acute pancreatitis with gall bladder conditions has long been fully recognized.

Cirrhosis of the liver is given as the cause of 5 deaths, acute infection in fulminating cases 2 deaths, pancreatic asthenia 1 death and exhaustion 4 deaths.

Pneumonia and acute pulmonary complications account for 53 deaths. In the writer's series, pulmonary complications accounted for 6 per cent of the deaths, whereas in the literature pneumonia is given as the cause of death in approximately 12 per cent of the cases. Unquestionably pneumonia is one of the most important of the dangerous complications of gall bladder surgery. Its high incidence in this field of surgery is probably depend-

ent upon a number of factors, such as the relatively advanced age of a large proportion of the patients, the high incidence of obesity and the fact that following the operation free movement of the diaphragm is often painful. It is the writer's opinion, however, that the pneumonia as listed in the cases collected from the literature was often a purely terminal event rather than a primary determining cause of death. As already stated, I would be inclined to transfer to the high temperature rapid death group, 2 of the 6 cases in my series listed as pneumonia. If the high temperature rapid death syndrome proves to be a true clinical entity, it seems probable that in the future a good many cases now listed as terminal pneumonia with the diagnosis based largely on a high terminal respiratory rate will be classified as high temperature rapid deaths.

Cardiac and myocardial conditions are given as the cause of death in 34 cases. Considering the age, obesity and general condition of many of the patients, this appears to be a low incidence for this type of death.

Renal failure, chiefly anuria, is given as the cause of death in 24 cases.

Diabetic coma is mentioned as the cause of only 1 death. Considering the frequency of diabetes during the age periods which furnish most of our gall bladder patients and the supposed relationship between chronic pancreatitis and cholecystitis, the extreme rarity of diabetic coma in association with gall bladder surgery is, I believe, worthy of emphasis.

Among the other miscellaneous deaths associated with conditions not directly related with the gall bladder, there was 1 death from thyroid intoxication, 1 death from thrombosis of the iliacs and vena cava, 4 deaths from complications of other operations, 2 deaths from cerebral hemorrhage, 1 death from acute hepatitis associated with alcoholism and 2 deaths from acute mental conditions.

Twelve deaths were listed as due to undetermined causes.

RIGHT-SIDED TRAUMATIC HERNIA OF THE DIAPHRAGM

OBSERVATIONS ON A CASE*

FRANK N. DEALY, M.D., F.A.C.S.

NEW YORK

IN the mass of surgical conditions commonly met, diaphragmatic hernia in itself is still so sufficiently infrequent as to arrest attention. At the Mayo Clinic it is said to occur once in 23,000 cases, and as in a series of 276 cases collected by Lacher it was found to occur on the right side in only 15 per cent of the total, the assumption that a right-sided hernia is sufficiently unusual to merit reporting may be justified.

The fact that most diaphragmatic hernias are left-sided is due partly to the protection on the right side afforded by the bulk of the liver. Occupying as it does the right dome of the diaphragm, the liver serves as a barrier at this site to the passage of abdominal contents into the right pleural cavity. The structure of the diaphragm itself however, is also of importance in favoring the preponderance of left-sided hernias. Arising from fleshy muscular slips from the ribs and sternum on the sides and anteriorly, the crura and arcuate ligaments posteriorly, it is inserted into a trilobed central tendon. This tendon occupies proportionately more of the right and anterior aspects of the diaphragm than it does of the left vault. Muscle fibers which can be separated or split offer less resistance to the passage of a hernia than tendon, and as the left lobe of the central tendon is the smallest of the three, there is proportionately more opportunity for a hernia to develop on the left side than anywhere else.

Hernias tend to protrude through the diaphragm at the site of normal apertures, such as the foramina of Morgagni at the junction of the sternum and the seventh costal cartilage on each side, and the foramina of Bochdalek, posteriorly, between the lumbar and costal divisions of the

diaphragm. Their most common site however, is through the esophageal opening. This aperture, slightly to the left of the midline and one of the three large normal openings of the diaphragm, is elliptical in outline and is the only one of the three that is muscular in structure, thus lending itself to dilatation from increased abdominal pressure beneath. The opening for the vena cava at the right is protected by the liver and is tendinous in structure while that for the aorta besides being of a tendinous nature, formed by the decussation of the crura, is really behind rather than in the diaphragm. These considerations probably account for the fact that while diaphragmatic hernias through the esophageal opening are the usual type, none has ever been reported as occurring through the opening for the aorta or the vena cava, and that while hernias in general usually enter the left chest and often force their way into the posterior mediastinum, they are rarely seen occupying the right pleural cavity.

Diaphragmatic hernia usually is divided into the following types: congenital, acquired and traumatic, a differentiation which is important not only from the standpoint of the suitability for surgical treatment, but in these days of compensation awards, from the standpoint also of the part that industrial accidents may play in their production. In the congenital type, and in such cases there may be congenital defects elsewhere, there is imperfect development, with lack of fusion of component parts of the diaphragm, with resulting open defects through which abdominal organs make their way into the thorax. Such hernias have no sac. In the acquired type, the hernial mass, covered

* Submitted for publication January 28, 1930.

by peritoneum and parietal pleura, forces its way between the muscle fibers of the diaphragm at a weak spot, usually at the site of a normal opening, until it comes to occupy a thoracic position while the traumatic cases arise from injury of the diaphragm, the result of stab or gunshot wounds, fractures of ribs, falls or crushing injuries of the thorax or abdomen. Traumatic hernias are usually at the periphery, whereas the other types are commonly centrally located.

In a succinct analysis of 378 cases in which operation was performed, 19 of which were at the Mayo Clinic, Hedblom found even on excluding the war cases, that most diaphragmatic hernias are traumatic in origin. His figures are as follows:

| | Per cent |
|--------------------|----------|
| Traumatic..... | 60.1 |
| Congenital..... | 14.7 |
| Acquired..... | 14.8 |
| Indeterminate..... | 10.3 |

Thus, as he states, of reported civilian patients operated upon, two-thirds of the cases are traumatic, one-sixth congenital and one-sixth acquired. In a considerable number of the traumatic cases however, there is a latent period between the injury and the onset of symptoms, and in a large proportion, months or years may elapse before operation.

In eventration of the diaphragm, which is not a true hernia at all, owing to extreme atrophy, with fatty degeneration of the muscular fibers, the diaphragm like a thin membrane yields to the pressure of the stomach and intestines below it, and together with them is displaced into the thorax. This condition may be the result of insufficient muscular development, may be due to trauma, may result from injury to the left phrenic nerve or be a part of a poliomyelitis. Surgical treatment is obviously futile and the difficulties of a correct diagnosis apparent.

One peculiar type of diaphragmatic hernia, the so-called paraesophageal type, of which up to 1924 only 6 cases had been reported in the literature, is probably the

result of a congenitally short esophagus. One such case at autopsy showed the esophagus to be 19.5 cm. in length from the cricoid cartilage (normal average length 23–25 cm.), with the fundus of the stomach herniated through the esophageal opening, lying in the right chest, the greater curvature to the right, the lesser to the left and the pylorus extending back into the abdomen through the hernial opening. Moreover, 3 cm. above the hernial opening was a perforation of a gastric ulcer! This type of hernia is mentioned here only because of the futility of surgery in such a case, as due to the shortness of the esophagus reduction of the hernia is impossible. It seems proper therefore to determine pre-operatively by x-ray the length of the esophagus in cases of diaphragmatic hernia as a guide to the possibility of surgical relief.

The symptoms of a diaphragmatic hernia of any type fall into two main classes, abdominal and thoracic, for there is not only an impairment of function of the abdominal viscus imprisoned in the hernial mass, but an interference as well in the free action of adjacent organs both thoracic and abdominal. The urgency of symptoms does not depend so much upon the size of the hernia, as upon the degree to which it has become adherent, its effect upon the esophagus blocking it or causing an incompetency of the cardioesophageal opening or its obstructive effect upon the stomach or bowel.

Substernal pain, vague gastric distress, vomiting and constipation are the commonest symptoms referable to the gastrointestinal tract. These symptoms may come on only at night, when the patient is lying down, or there may be morning vomiting or acid regurgitation due to incompetency of the cardioesophageal opening. Dyspepsia or indigestion may occur and give rise to a tentative diagnosis of ulcer or gall bladder disease. There may be attacks of recurring intestinal obstruction or there may of course be evidences of strangulation.

Among the thoracic symptoms cough and cyanosis are probably the most common. Dyspnea is not so frequent, but may occur along with pain, palpitation, hiccup and other symptoms of thoracic intrusion.

These various symptoms both thoracic and abdominal, may of course be present from the onset with all the evidences of shock to complete the picture of a serious trauma. Prompt intervention may be demanded. On the other hand, the symptoms may gradually develop, certain ones predominating according to the type and location of the hernia. Or, at some subsequent date, after a quiescent period an emergency may suddenly arise. So long as strangulation does not occur, the presence of abdominal organs within the chest is not incompatible with life, but ordinarily such a condition does incapacitate an individual, impairs health and in many cases terminates in strangulation.

Like that of many other conditions, the diagnosis of a diaphragmatic hernia often depends primarily upon the suspicion that it may be present. It is often missed because not suspected, but with its possibility in mind a careful history should be made, with proper evaluation of the symptoms and a search for or discovery of suggestive signs. The diagnosis should at least be suggested even before resort to the x-ray. The commonest signs are:

1. Tympany or dulness over the lower thorax.
2. Splashing or gurgling sounds, due to distended stomach, and
3. Heart displacements, usually dextrocardia.

The presence or absence of Litten's sign, asymmetrical movements of the costal margin and variations in the subcostal angle, as emphasized by Hoover, often assist in the differentiation of conditions characterized by elevation or depression of the diaphragm, as for instance, in the differentiation between subphrenic abscess and pleural effusions. But they may also be of value in determin-

ing impairment of the diaphragm due to the presence of hernia.

The x-ray of course, is of vital importance. In the ordinary x-ray of the chest however, the shadow may be mistaken for pneumothorax, pulmonary abscess, tumors of the thorax, thickened pleura, pleuritic bands, esophageal diverticula and other conditions, so that unless the possibility of a hernia is suspected, with the subsequent administration of an opaque meal, the diagnosis still may be missed. In every case of penumothorax or dextrocardia, hernia of the diaphragm should be suspected until disproved.

To make the diagnosis in these cases is of considerable importance for two main reasons. In the first place, as the existence of a diaphragmatic hernia often gives rise to symptoms common to other abdominal disorders, a correct diagnosis will prevent needless operations on other organs; in the second place, in those cases amenable to surgical treatment, a correct diagnosis with reparative surgery will forestall incarceration with its vastly increased operative mortality. Many of these cases, especially of the traumatic type result sooner or later in intestinal obstruction and strangulation. In Hedblom's series, 33 per cent of the cases strangulated and in 36 cases not operated upon, Lacher states that strangulation occurred with a fatal outcome as follows:

| | |
|----|----------------------|
| 5 | on the first day |
| 10 | within a month |
| 5 | within five years |
| 5 | within twenty years. |

Thus it is evident that strangulation, whether early or late, is a distinct menace and its prevention is a sufficient indication for operative interference.

The operative approach in the diaphragmatic hernia is thoracic or abdominal or a combination of both, with the lowest mortality occurring in the thoracic operations. In cases of obstruction in which the cause is uncertain, a laparotomy of course is indicated. If a hernia is known

to exist and the opening in the diaphragm has been shown to be parasternal, a laparotomy here also is best suited to meet the conditions. Otherwise the thoracic route is usually preferable, gives a slightly lower mortality and offers a better chance for a successful closure of the hernial opening. In Hedblom's series, the total operative mortality was 33.6 per cent, that in obstructed cases being 53.1 per cent and in the non-obstructed cases 23.4 per cent. According to the operative approach, the mortality in laparotomies was 42.9 per cent, in thoracic operations 19.8 per cent and in the combined operation 26 per cent. The cause of death in most cases is shock, next in importance in the laparotomies being peritonitis, and finally in both types of operation empyema and pneumonia. Pleural effusion is the commonest complication in either type, which is frequently non-purulent but may go on to empyema.

The reduction of the hernia is often difficult as indicated by the numerous procedures resorted to for that purpose. Digital dilatation or incision of the hernial ring, deflation of the stomach by means of a stomach tube or even aspiration through the gastric wall, resection of the omentum and the induction of pneumothorax to overcome the suction effect of the negative thoracic pressure have all been employed. It is possible that spinal anesthesia by its lessening of the caliber of the gut might also be of material assistance in facilitating the reduction.

If reduction is impossible, a gastroenterostomy is sometimes indicated, or enterostomy in cases of obstruction. When possible the hernial opening should be repaired by suture or some plastic procedure, or if it cannot be completely closed, the omentum, stomach, spleen, liver or colon may be sutured to it to close the gap and prevent recurrence. The aspiration of air from the pleural cavity at the completion of the operation will facilitate the expansion of the lung.

CASE REPORT

G. B., an adult Swede, fifty-three years of age and a carpenter by occupation, admitted to the Mary Immaculate Hospital, Jamaica, N. Y., on March 11, 1929. While framing a second-story window, he had slipped and after a fall of 14 to 16 feet, had landed across a 3 in. beam striking and severely injuring the right side of his chest. After being brought to the hospital in a moderate degree of shock, he was able nevertheless to walk into the ward, though slightly cyanotic, with an irregular pulse of poor quality and complaining of severe pain in the right chest. Occasional coughing spells with an expectoration of thick, yellow mucus, accompanied by cyanosis and rapid, shallow respirations, were a definite feature of his initial symptoms. When he was admitted, examination of the chest showed a slight deformity in the contour of the right side with apparent depression and limitation of motion on respiration. Tenderness was marked and on palpation subcutaneous emphysema was elicited as well as crepitus over several ribs. On percussion there was hyper-resonance over the lower right chest posteriorly and especially in the midaxillary line. The apex beat of the heart was in the sixth space, 5 in. from the midsternal line. At this time there was no suspicion of a diaphragmatic injury, though moderate rigidity of the abdominal muscles in the right upper quadrant together with the character of the injury and the patient's general condition naturally suggested the possibility of trauma to the liver, kidney or other abdominal organs. There seemed however, no indication for operation, though patient vomited several times and in fact, for the first three or four days vomited persistently. The admission blood count showed a leucocytosis of 15,000 with 85 per cent polymorphonuclears.

An ordinary x-ray of the chest as taken the following day, the report of which was as follows: "Fracture of the 2nd rib in the midaxillary line. Comminuted fractures of the 10th and 11th ribs $1\frac{1}{2}$ inches from the spinal articulation. Fractures of the 7th, 8th, 9th and 10th ribs in the mid-axillary line with moderate displacement of the fragments. The costophrenic angle on the right side is moderately obscured. Above this is an area of diminished density, greatly simulating a pneumothorax. The right lung is displaced upward and inward toward the mid-line." Aside therefore, from

the diagnosis of multiple fractures of various ribs and the presence of an exudate, probably sanguinous, in the right chest cavity, there

A few days later when the patient was able to tolerate it, a barium meal was given and a gastrointestinal series made, the presence of a

the hospital, his condition gradually improved, but for three months after his discharge patient had occasional vomiting spells lasting sometimes two days. Since then he has now been free from vomiting, but he still complains of pain, occasional cough and shortness of breath on exertion. Expansion of the right chest is still impaired, breath sounds are still diminished at the right base, there is dullness posteriorly up to the sixth rib, the liver dullness anteriorly is normal, but between the two in the midaxillary line is a definite area of tym-

and from the compensation standpoint, in spite of the history of extensive injury, multiple fractures of ribs at the site of hernia, the development of hemothorax, the symptoms of cough and vomiting together with cyanosis, and the demonstration of a hernia through the periphery of the diaphragm, the question is still being argued as to whether the hernia if it exists at all, is traumatic or congenital.

[NOTE: For references see author's reprints.]

THE ROENTGEN-RAY DIAGNOSIS OF POLYPI OF THE MAXILLARY ANTRA*

HOWARD P. DOUB, M.D. AND ANDREW R. MCGEE, M.D.

DETROIT, MICHIGAN

THE roentgen-ray examination of the paranasal sinuses is being used so extensively that it has become almost a routine procedure by many rhinologists in cases where there is the slightest doubt as to the pathology present. This is especially true in those cases where one is searching for a hidden area of focal infection. A considerable percentage of such cases are without symptoms and the x-ray is used for an analysis of the anatomic and pathologic picture.

Polypi of the maxillary antra occur much more frequently than was formerly believed. This difference in the number found has largely been brought about by the evidence disclosed by the roentgen examination. These polypi may be seen in profile by plain films of this area or indirectly by the pressure defect produced on a column of an opaque medium injected into the antrum.

The structure of the mucous membrane of the antrum is such that, when it is exposed to acute and chronic inflammation, polypi are prone to develop locally. These polypi may or may not be associated with nasal polypi, but are more apt to be sessile than pedunculated as is often the case with nasal polypi. They may fill the antrum and protrude through the orifice and give the appearance of nasal polypi, in which case, of course, intranasal excision is of no avail. Much debate has ensued over the question of the relationship of these polypi to true neoplasms; but it is impossible here, as elsewhere, to differentiate clearly between the products of chronic inflammation and neoplasms.

Grossly, they are usually a mass of soft, edematous, polypoid tissue having a somewhat pinkish color. They may, however, be tough and stringy with a more

solid consistency. They also frequently show lobulation. Microscopically they are often covered with columnar epithelium which may show some desquamation. The glandular structures may show hyperplasia. There is usually an inflammatory edema present. Sometimes the cellular infiltration predominates and sometimes the edematous reaction is more marked. Eosinophilic infiltration of high degree is often present.

The relationship between chronic disease of the paranasal sinuses, and upper respiratory infections, various lung conditions and asthma has been repeatedly described. It has been found that it is in these cases of chronic sinus disease, where the symptoms of the disease are so slight and where the washings from the antrum often return clear, that one must look for the source of many secondary diseases of the respiratory tract.

There is little doubt that many cases of these polypi and mucocoeles are the result of chronic inflammatory processes in the antrum. The amount of polypoid formation, however, is not always in proportion to the amount of secretion present. Some have observed that in the pronounced suppurative processes one is less likely to find this condition than in the mucopurulent affections. In certain cases with very large polypoid growths secretory disturbance may be scanty or absent.

The best position for examination of the antra is that described by Waters and Waldron¹ in which the chin rests on the film holder and the nose is raised sufficiently to throw the base of the skull below the antra, thus giving an unobscured view of these. The lateral view is also useful in certain cases.

*Submitted for publication March 27, 1930.

Formerly plain films were made of these areas but since the introduction of lipiodol, by Sicard and Forestier, in 1922, for the

antrum obliterates the shadow of the polyp on the roentgenogram. In such cases the rounded pressure defect of the

packing in the nose, the patient can then be transported to the x-ray department without any appreciable loss of the opaque medium.

FIG. 8. A case of polyp on medial wall of right antrum shown only by lipiodol.

but they may occur in any part of the antrum. A clouding of the entire antrum, especially if of uneven density, in a patient

with chronic recurrent infection usually means polypoid formation, and it is in this class of patients particularly that lipiodol is of value. The lipiodol injection also shows the thickness of the mucous membrane lining of the antrum with an exactness that can be obtained in no other way. In some cases with the aid of lipiodol a thickened mucous membrane will be found with only one small area showing beginning polypoid degeneration.

In a series of these cases in which we have reported antral polypi from plain films 21 cases have been operated upon and the diagnosis confirmed in 19 cases, or 91 per cent. It might be noted here that in one of the two unconfirmed cases, the operative notes are such that one might infer that some polypoid tissue was removed although it was not definitely named as such. In this case the roentgenogram was usually definite.

In another series in which the diagnosis of polypi was made with the aid of lipiodol 20 cases were operated and polypi removed from 19 of these cases with a correct diagnosis in 95 per cent of the cases.

In still another series of 15 cases the diagnosis was made from the plain films and confirmed after lipiodol injection. At operation all of these cases yielded polypi with a correct diagnosis of 100 per cent.

From this series it is seen that a correct

diagnosis can be made from the roentgenograms in a very high percentage of cases. In a series reported by Drea,² using plain films only, there were 19 operative cases with polypi found in 18, or 95 per cent. In a series of 7 operative cases reported by Waters and Doub³ polypi were found in 5 cases and mucocoeles in 2 cases. Inasmuch as a differential diagnosis between these cannot be made from the roentgenogram, this would be counted as 100 per cent correct diagnosis.

SUMMARY

From a review of the literature and of our cases, it becomes evident that the roentgen-ray examination of the maxillary antra is a very definite aid in diagnosis, particularly in those chronic cases with few localizing symptoms. An additional advantage is gained by an examination following the injection of the antrum with lipiodol. Polypi of the antra and thickening of the mucous membrane are shown with a high degree of accuracy as proved by the reported operative statistics.

THE X-RAY DEPARTMENT OF A TEACHING HOSPITAL*

JAMES T. CASE, M.D.

CHICAGO, ILLINOIS

FOR two decades or more the subject of this symposium has been under discussion by teachers of radiology, so it is scarcely to be hoped that in today's remarks anything essentially new can be added. Rather, we may hope to crystallize thoughts advanced on various occasions at meetings of the national societies devoted to the specialty of radiology and at previous meetings of the nature of the present one, sponsored by the American Medical Association, the American College of Surgeons and the American Hospital Association.

The teaching of radiology is a subject on which complete agreement has not been reached. That it should be taught is taken for granted, but how much effort should be devoted to making radiologists out of undergraduate students, or even graduate students not specializing in radiology, is not agreed upon. Undergraduate, and even graduate, teaching requirements differ much from those of institutions or departments devoted to the instruction of prospective radiologists. The latter require knowledge of a wealth of detail relating to technical matters, electrical and mechanical principles and apparatus involved in the production and manipulation of the roentgen rays, as well as the needed medical training and experience. Further, the radiological specialist must spread this training and experience over a large field, embracing almost every branch of medicine. Like pathology, medical radiology finds application in a large percentage of patients; indeed, radiology may be likened to pathology *in vivo*. It is patently impossible in any scheme of undergraduate or rotating internship teaching to expect to give the student the necessary preparation to practice radiology.

The purpose, then, of a department of radiology in a teaching hospital should be to furnish the appropriate assistance in the routine examination and therapeutic management of patients; to participate in staff conferences; to contribute to the instruction of internes and undergraduate students on the application of radiology to the problems of diagnostics and therapy—on the possibilities as well as the limitations of the roentgen ray aid; to help in various research problems as they present themselves; and to assist in post-mortem examinations.

Parenthetically, it is proper to call attention to the fact that the hospital management should not look upon the radiological department as a profitable investment, and it should not be the aim of the department to contribute to the financial standing of the institution until all the foregoing objects have been achieved. There is no more justification for the hospital to capitalize the experience of the radiologist, than to put the operating room on a fixed fee basis, pay the surgeons and nurses salaries, and credit the profits to the income of the hospital.

In order to meet the foregoing aims, the physical equipment of the hospital should include standardized x-ray equipment for radiography and fluoroscopy and for x-ray therapeutic work, housed in rooms of sufficient size to permit demonstrations to students and internes. Instruments for biplane fluoroscopy to be employed in the setting and splinting of fractures, a combined roentgenoscopic and roentgenographic cystoscopic table, a special table for gynecological x-ray studies, such as salpingography, hystero-graphy and inflation of the uterine tubes, and proper equipment for high tension deep therapy are

*Department of Radiology, Northwestern University Medical School.
Presented at the Annual Congress on Medical Education, Medical Licensure and Hospitals, Hospital Department of Radiology, February 19, 1930.

almost necessary in a large hospital, whether or not employed for teaching students.

The personnel must include a medical radiologist, with such physician and lay assistants as the volume of work demands. The larger hospitals may justify a staff of radiologists, so that under the director of the department, who may elect some specialty of medicine in which to expand his radiological effort several associates may be developed with special aptitude in the radiology of other specialties, so that the entire field of medicine may be covered with a maximum of radiologic service.

The hospital management must not look upon the radiological department merely as a photographic center for the production of pictures to be interpreted by the various surgeons, internists or other specialists who may have ordered the x-ray studies. There is a growing tendency to look upon the x-ray department as just such a photographic center, where patients are sent to have roentgenograms made, after which the resulting concrete records are asked to be sent to this or that ward or to this or that office, where the original referring physician often appears to be willing to make his own readings and seems perfectly content to assume full responsibility for the radiological diagnosis. Precedent for this was established long ago in regard to roentgenograms of fractures and dislocations, and often times with foreign bodies, and has come to be considered in many quarters as the perfectly proper procedure for the orthopedic department; but we should recognize it as the beginning of a new departure. We should look well ahead to see whither it leads. Does it mean that the chest films are to be sent to the chest department, the gastrointestinal films to the gastroenterological department, the head films to the neurological department, etc.? If so, what other future can be seen for the roentgen department than as a photographic laboratory, and what need for an experienced physician-radiologist

in such a place? Such a scheme would scrap the benefits of fluoroscopy, unless the radiological department, like an operating room, be opened to all members of the hospital staff, and, even then, the average efficiency of the screen work would be low. My firm belief is that such a development would result in setting back the clock of radiological progress many years, for it would mean abandonment of all help obtainable from screen examinations by a physician-radiologist with his accumulated experience of many years in examining patients from all departments of a hospital. There is little tendency for the radiologist to fall into a rut, to see problems from a single angle, for he is constantly influenced by the diverging opinions of his colleagues in all departments of the hospital, and has a better opportunity than most physicians to realize fully the fault of getting into a rut, and the need of maintaining a receptive mind.

The above remarks should not be interpreted as intimating that an internist, a surgeon, or any other specialist has not a perfect right to fit himself in every possible way for the practice of this specialty; and if he wishes to utilize the roentgen rays as one of the methods of examination, there can be no logical objection raised to his use of this procedure. It is his need to see that he has had sufficient training under expert tutelage for the radiological work. But if the hospital should be so unwise as to divide up its radiological work, apportioning it out to various departments, there would be lost that great help to physicians, surgeons and radiologists, which comes from frank discussion of the roentgen findings, both screen and film records, between radiologist and referring physician, and their proper evaluation in the light of the clinical aspects of the case brought out in such a discussion.

The reports of x-ray findings should be full of details, but every such detailed record should also contain a line or two of summary for convenient quick reference

and for cross-indexing. It is our custom to attach a copy of the report to the patient's chart, where it is available at all times for study by the students, internes and clinicians, and also to affix a carbon copy of the report to the x-ray department folder containing whatever film records are filed. Cross-indexing provides a means of aiding in research and follow-up, both of which are essential in teaching institutions. The complete record of observations in the detailed report already referred to may prove of great value in future research problems and should form a part of the permanent case records.

The roentgenological diagnosis must be arrived at by a process of reasoning and argument, just like the clinical diagnosis. The films do not come out of the dark room with diagnosis labels filled out. By a process of considering all the possibilities and eliminating them until the probable diagnosis remains, the roentgenologist reaches a conclusion. He may not be able to put a name to a condition which he studies, unless he draws upon other than roentgen evidences for his information, and this is something which I believe should always be done for the advancement of the radiologist but which should never be done in the written x-ray report. The roentgen report should contain only statements which can be substantiated from roentgen evidence. This report will then take its place with the other evidences of the case, from which the clinician in charge will then draw his conclusions; "*but*" (and this is a very important "*but*") if the staff has the slightest interest in the development of a capable roentgenologist with ever increasing usefulness, they will leave no stone unturned to keep him posted in regard to his cases, tell him of his success as well as his failures, send for him when the surgeon or pathologist has let the light of day upon a lesion which has been baffling.

In the light of what has been said, it is apparent that the examination and the interpretation of the examination findings will be all the more valuable and helpful

if the roentgenologist is furnished with the history and such clinical data as are available up to the moment of the roentgen study. This will enable him to focus his attention upon the probable lesion and will permit him to exercise some of the tricks which he may have learned to brush away the fog a little more efficiently than if he is merely asked to examine this or that tract. The roentgenologist, once proved to be a man worth cultivating, should not be treated as though he were a student perpetually on examination and each patient sent to him as a catch problem, but he should be looked upon as a colleague and be provided with every fact likely to assist him not only in the interpretation of the case in hand but also in his development into a better, broader and more useful consultant. The roentgenologist may render valuable help in the early diagnosis of postoperative ileus, in the discovery of subphrenic abscess and in the proper placement of drainage tubes. In post-operative pneumonias and other respiratory complications, the roentgenological films sometimes constitute decisive information. A sympathetic cooperation between the radiologist and the surgeon or internist in these types of cases will result in deviation from the old approved methods and result in valuable research in new methods and in new applications of old methods.

As Barclay has suggested, the roentgen department is full of intensely interesting work; it may be likened to a profusely illustrated book. The illustrations come automatically from all departments of the hospital and from outside patients. The value of the illustrations can be considerably enhanced if there is a close sympathetic cooperation between the pathologist and the roentgenologist; and it would be an advantage if the two departments were physically closely associated.

It transpires in most hospitals that a very large proportion of these cases find their way to the roentgen department, and if the pathologist and the roent-

genologist are working together there is thus afforded a great opportunity for these two workers to see that there is made the most possible out of the wealth of material which accumulates. In this manner, the roentgen department may constitute a bureau of information concerning material available from the unique position occupied by it as a link in so many diagnostic chains. Again quoting Barclay, the roentgenologist has a great opportunity

to help link up scattered units of a hospital which tend to get further and further away from each other, each absorbed in itself and not knowing what goes on in other units; and he should be able to break down barriers which have a tendency to spring up in big hospitals by making the x-ray department a common meeting ground for physicians from all departments of the institution. [For discussion of this paper see p. 1060.]

THE REQUIREMENTS OF A DEPARTMENT OF RADIOLOGY IN A LARGE MUNICIPAL TEACHING HOSPITAL*

P. F. BUTLER, M.D.

BOSTON, MASS.

THERE is no essential difference between a municipal hospital and an endowed one. Both hospitals have the same objects in view, to relieve suffering, study disease and train young doctors. Endowed hospitals may keep patients for a longer time while undergoing study. Municipal hospitals must discharge patients as soon after their recovery as is practicable. This is especially true of a municipal hospital which does not contain proportionately the requisite number of beds for the community.

For greater simplification the subject here considered is divided into the following chapters:

1. Organization
2. Physical plant
3. Fire hazard
4. Political interference
5. Health of workers
6. Abuse of department
7. Training radiologists
8. Teaching
9. Research

Organization: In the organization of a radiological laboratory of the large municipal hospital there must be a chief radiologist, medical assistants, medical internes, technicians, nurses and clerks, depending upon the size of the clinic. The chief should be a well-trained and experienced medical man with a sound knowledge of clinical medicine and surgery and, of course, must be an expert in radiology. The hospital must make it worth his while not only to take the risks of his calling but also to keep himself abreast of his branch of medicine. He must be responsible for all work turned out, materials used, upkeep of apparatus, selection of house officers and safety of patients and working force.

He should have the necessary medical assistants and so subdivide the work of the clinic that each assistant is responsible for his particular division. In some cases the chief should be a man who gives all his time to the laboratory, but this means a substantial salary and the privilege of charging private patients. Often this scheme is not practical and the problem is solved by a part-time man who may still carry on his private practice. Smaller hospitals may be run on a percentage basis but this cannot be done in a municipal hospital because the percentage of non-paying cases runs from 70 to 90 per cent of all the cases seen and furthermore the private patients are usually those who cannot afford to pay more than a small fee. The assistant physicians in the department should not be expected to spend more than a half day because they could not be paid enough to reward them for their time. The resident radiologist, a young graduate, should give all his time and be paid a reasonable salary. The internes are paid in some hospitals but are not as a general rule. One assistant physician should be responsible for all material bought and used and make a monthly report to the chief. Another is responsible for the proper upkeep of apparatus and meters. The resident radiologist, who should be a graduate radiologist, is responsible for the conducting of the department in the absence of the visiting staff. Technicians may be male or female. It has been our experience that hospital work is too exacting and trying for female technicians, and we have found that male technicians accomplish more even though they are not as amenable to discipline. There is now a registry for technicians which is

* Presented at the Annual Congress on Medical Education, Medical Licensure and Hospitals, Hospital Department of Radiology, February 19, 1930.

endorsed by the Radiological Society of North America, where competent registered technicians may be obtained. The technical staff should be instructed in the theory, practice and dangers of the work. The efficient department gives twenty-four-hour service; therefore a night technician or interne must be available at all times for emergency work. The value of this service is frequently seen, for instance, in cases of children where diagnosis can only be made by x-ray as between a central pneumonia and acute appendicitis.

Physical Plant: Roentgen-ray apparatus is expensive to buy and to maintain. Most of the modern x-ray depends largely upon the type of clinic and the personal experience of the radiologist. A general clinic requires several different types of apparatus and it is advisable to have separate rooms, where possible, for gastrointestinal work, chest work, renal work, etc. The installation of apparatus should be supervised by a radiologist who is conversant with all the requirements and dangers of the work. This should never be left to the dealers alone. The current may be direct or alternating. It may be supplied by the hospital power plant or brought in from the local electrical company. Which ever is used, there should be a free single line to the x-ray department with no elevators or other machines on it. This main line must be made of sufficiently large copper wire to obviate any appreciable loss of current. A recording volt meter on the incoming line near the main switchboard keeps accurate record of the voltage delivered to the department. The main switchboard should be in a dry, accessible location. All switches should be labelled and of the safety type. A separate wire from the switchboard to each room insures against breaking down in more than one room. All wires should be carried in conduits. Each operating room should have its own wall switch. At night the main power switch on the central board should be cut out, disconnecting all machines in the department. This is necessary to

guard against outsiders turning on machines during the night and is also a wise precaution in case of fire. Throw switches connecting two rooms with high tension electricity should not be allowed. Portable machines are necessary for examining patients who are too ill to be brought to the department. The actual care of each machine is in charge of its individual technician and once a month all of the machines need servicing by regular service mechanics from the dealer. Every meter should be calibrated once a week with a standard meter. The standard meter should be calibrated about every four months by the manufacturer. Standardization of machines and tubes so as to give as nearly uniform a technic as possible is the ideal method for a large department. Charts posted over the control cabinets giving definite settings for each examination make this possible. The technicians should be required to follow these charts. This means great simplification of the developing room work because time developing of large numbers of films is thus made possible.

The location of the department should be central in the hospital plant, so as to be readily available to all other parts of the institution. The following table illustrates the distribution of cases in our hospital for the year 1929 and emphasizes the need of a central location:

| | |
|-----------------------------------|--------|
| Total ward patients..... | 19,463 |
| Total out-patients.... | 14,385 |
| Total outside doctors' cases..... | 4,083 |

The department should be arranged so as to allow a continuous flow of patients in one door and out another, thus avoiding congestion. Because of the high cost and intricate mechanism, roentgen-ray machines should never be placed in dark or damp places, especially basements. The apparatus must be accessible at all times for workmen. It also is particularly susceptible to dampness. High tension wires attract dust and quickly become fouled unless constantly kept clean. The department is best placed on the first and second floors with ample window space and

ventilation. Elevators should be large enough to carry a ward bed patient with both legs in abduction plaster apparatus. Sliding doors are preferable to swinging ones. The walls should contain thin sheet lead to a height of about seven feet. Control machines are best placed behind lead or lead glass shields, so as to compel the technicians to retire behind this protection while making exposures.

Ventilation and sunlight in every room are quite essential. Some observers believe that poor ventilation and lack of sunlight have contributed more to ill health among roentgen-ray workers than any other cause. Certain it is, that since x-ray departments have been moved out of dark basements, the incidence of impaired health among the workers has greatly lessened. The best arrangement for ventilation is to have an exhaust fan in every room which draws out the foul air through ventilating shafts. This should be supplemented by openings above each window, which may be regulated, for admitting fresh air from the outside.

For dressing rooms the best plan is a row of steel lockers adjoining a small dressing room. The patient undresses in the dressing room, puts on his hospital gown and then places his clothing in one of the steel lockers and locks it. This arrangement does away with the necessity of large dressing room space. It also prevents theft and contamination of one patient's clothing by that of an unclean person.

Fire Hazard: This subject cannot be emphasized too much. There should never be a repetition of the frightful holocaust which occurred earlier this year. In spite of all the investigations and reports arising from this tragedy many communities are still as open to disaster as they were before. Many excellent recommendations were made for the prevention of fire and explosion and it is almost criminal not to follow them. Fire and explosion from x-ray films in a hospital filled with bed-ridden patients is unthink-

able, but can we all say that such a calamity can never happen in our own hospitals. If the safety type of film is used the fire hazard is negligible. As a matter of fact, this film is no more dangerous than so much office stationery. The nitrate film should not be allowed in any institution. It is highly combustible, gas-producing and explosive. The safety type of film costs about 20 per cent more than the other, but the added expense is good insurance against fire or explosion. Water is the most efficient agent against fire. Therefore, the entire department should have a first-class sprinkler system, with extra large supply pipes and oversensitive sprinkler heads. Windows in film storage rooms should be made of very thin glass so that they will blow out easily in case of fire, thus letting the smoke and gas out into the air. Fire hose and extinguishers should be placed at strategic points throughout the department. No smoking is allowed. Automatic fire alarms are helpful. Current films must be kept in the department for handy reference but all other films should be stored in a fire-proof out-building. In our state the statute of legal limitation for law suits is six years, and because of this we preserve all films for seven years. Films older than that are not of much use in a given case anyway, because of the changes occurring in most physical conditions over that period of time.

Political Interference: This is largely a bugaboo. From my own experience and that of others in similar positions, it is only fair to say that there is no more meddling by politicians than there is by favored friends in other hospitals. We have been told by men of prominence in political life that practical politicians never wish to meddle with hospital organizations or interfere with their purchase of supplies and equipment. All positions should be under civil service regulations. These regulations allow the head of the department ample latitude in selecting his technical help and eliminate the undesirables from

consideration. Selection and purchase of equipment should be in the hands of the director. If he has the confidence of the hospital authorities in his judgement and integrity there should be no difficulty in these matters. There is generally an ordinance requiring that all purchases above \$1000 must be let out on bids. This situation is easily handled by incorporating careful specifications for the bids. The specifications used by the army and navy are excellent models to follow.

Health of Workers: The first concern of the radiologist must be the safety of the patient. Each radiographic patient, however, receives such a small amount of exposure that there is practically no danger of over-exposure. The treatment cases, on the other hand, must be surrounded with all the necessary precautions. All treatments must be supervised by one of the radiologists, who understands the dangers. All workers with roentgen ray or radium should have ample time off from duty. One month each year is not too much. They should be instructed to spend as much time as possible out in the sunlight. This vacation problem is a difficult one when working for a municipality, because as a rule vacations are regulated by city ordinance. This ordinance permits of no exceptions and is unfair to workers in hazardous occupations such as ours. Radiologists and their technical help must be watched for signs of physical breakdown. Regular blood studies should be made to discover signs of blood disturbance. If this condition is found, a quick vacation is the best method of treatment. A fairly reasonable amount of sick leave is granted by most cities, but it is not enough for those in hazardous occupations as those filled by our technical help. The United States Government allows all its employees thirty days a year for vacation and the same allowance for sick leave. This is about what our technical help should receive. Responsibility for the health of the working staff is a worrisome burden and the chief of the depart-

ment should be allowed more latitude in regulating their working hours. A recent court decision in New Jersey has placed this responsibility directly upon the employers in a radium factory. If then, we who employ people in this dangerous work are liable for their health we should be allowed to use all the necessary safeguards against physical breakdown. Perhaps I am over-emphasizing this aspect of the problem as far as x-ray workers are concerned, but I cannot place it too strongly before you when radium workers are concerned. The safety measures for x-ray workers are now quite well understood:

1. Lead-lined booths for operators.
2. Lead glass bowls for tubes.
3. Lead-enclosed tubes.
4. Ample distance of tube from operator.
5. Good ventilation and sunlight.

If these simple precautions are taken there is practically no danger to the operators. The radium problem, however, is not so easily handled, especially where the operator must handle needles, either of salt or emanation. These operators must be carefully watched for breakdowns in health.

Abuse of Department: The tendency to send cases for roentgen-ray study before being properly worked up is wrong. It lessens the diagnostic acumen of the referring physicians, especially the younger men. It requires the x-ray department to make many unnecessary examinations and hence is an expensive waste of time and material. Furthermore, when these internes go out into private practice they may be located where an x-ray equipment is not available and, therefore, they must make their diagnoses without the help of x-ray.

The signing of requisitions should be done by the visiting physician, except in emergency cases, when the resident or senior house officer may sign them. They must not be signed by medical students or junior internes. Executives in the main office also are allowed to sign them, but they are apt to call for unnecessary examinations, especially after people persuade them

that they wish an x-ray examination. Last year in our gastrointestinal division 50 per cent of the cases showed negative findings. It is reasonable to assume that a large percentage of these were booked for examinations unnecessarily. Our department history taker (a medical student) estimates that about 25 per cent of the patients he interviewed did not require barium studies.

Another annoying problem is the loss of finished films from the record room. These films are taken to the bedside or operating room for convenience of the attending surgeon and are frequently misplaced and lost. My own feeling is that no films should be allowed out of the department and that the visiting physicians should all come to the central viewing room to study the cases in which they are interested. A possible solution for this is to make prints of the interesting cases and attach these to the clinical records, keeping the original films in the department.

It is an established principle that no hospital that is maintained by a state or city should make a profit from medical services rendered to any patient. However, it is advisable that private patients should pay a reasonable fee for private work. Misrepresentation by patients of their ability to pay is, of course, a serious consideration in all hospitals.

The principal means of cutting down expenses is by eliminating unnecessary examinations, which are the greatest cause of needless expenditures. We have derived considerable relief from this annoyance in our out-patient department, by establishing a gastrointestinal clinic: patients referred from any department for barium studies must go through this clinic first, where the need of a roentgen examination is decided. We are also called upon to examine poor patients referred for examination by doctors not connected with our staff. This service is not very large, because all these cases must pass through the hands of one of the executives, who

decides whether roentgen examination is really indicated.

Training Radiologists: Up to a short time ago there was more or less difficulty in obtaining high class internes who wished to take up radiology as a specialty. The reason is that the specialty has not yet reached the high place in the minds of medical men that it deserves. This is not true of physicians in contact with good radiologists, for here the true value of the x-ray department as a consulting service is appreciated. Physicians not in touch with good radiologists have an idea that the work consists mostly of picture taking and that anyone can read a roentgen-ray film. This is the principal reason why commercial laboratories are flourishing. As soon, however, as these physicians become acquainted with trained radiologists and appreciate their value as consultants, they see at once that this specialty is a real medical aid in helping to solve their problems.

An interne in radiology should receive at least one year's training. He should preferably be a hospital graduate. This training begins with a course of study and practical work in the technical aspects of developing, lantern-slide making and construction of machines; in other words familiarity with chemistry, physics, electricity and other fundamental subjects. He should do all the emergency work, nights and holidays, at first under supervision but later on, when qualified, alone. He also serves under the different visiting radiologists so as to benefit by their personal ideas and experience. He should work out one original problem during his internship. He is required to follow interesting cases to the operating or post-mortem rooms. In short, his time should be carefully laid out so that after learning the fundamentals he gradually works up and through all the divisions of the work. It is also a good idea to give him some of the responsibility in buying supplies and overseeing the care of machines so as to round out his general usefulness.

Teaching: Teaching should be done in all municipal hospitals. Its value as a stimulant to the staff in keeping up to date is undisputed. It would indeed be a pity not to utilize for teaching purposes the wealth of material passing through such a hospital. Nowhere else do we have the opportunity for handling such a large volume of traumatic cases as are brought to the hospital by public ambulances and the police. With the increasing number of automobile accidents each year it is quite essential to train the prospective doctor in the handling of its inevitable train of complicated accidents. A collection of teaching films and lantern slides should be a well developed part of the department. In fact, a good collection of this sort will prove its worth as a reference library of disease and injury. Most of these cases should be checked by biopsy, operation or autopsy findings so as to make them accurate and correct representations.

Another reason for the delay in radiology reaching its proper place in the field of medicine is the attitude of medical schools. Very few of them give this specialty the amount of time or attention in the curriculum to which it is entitled. Teaching is usually done under one of the other branches of medicine. Radiology should have a department of its own. Furthermore, the teaching of many of the other branches may be made more graphic and impressive by the use of the roentgen ray. It is the experience of most teachers of roentgenology that the physiology of the mechanics of the gastrointestinal tract is more satisfactorily demonstrated to students by this method than by any other. Certainly the normal architecture of the human skeleton cannot be shown as well

by any other means. Serial plates of lobar pneumonia and tuberculosis never fail to make a graphic impression on the students' minds.

No attempt is made to teach students roentgenology as a specialty. Rather do we try to have them correlate the abnormal findings with the clinical history and the physical findings in a given case. They are taught the value of interpretation and the amount of reliance to be placed upon it. They are shown enough to enable them to interpret an average film. A brief knowledge of its uses in diagnosis and treatment is about all that can be given to them in their third year. Elective courses for fourth-year students require at least one month's time. This course is more comprehensive and goes further into detail. Post-graduate teaching is given to radiologists who wish to keep in touch with the work of a large medical center.

Research: No specialty advances unless research work is being constantly done. As the specialty of radiology is one of the youngest of the medical sciences, the need and opportunity for research are unlimited. Each succeeding year sees newer uses for it. One of the greatest responsibilities of the older radiologists is to encourage and stimulate research problems. Many of the radiologists in the forward looking hospitals require one research problem a year from each of their internes and assistants. The problem may be a small one but if it contributes one new idea it is well worth while. The variety of cases seen in such an institution should be thoroughly studied for the benefit of medical science and the consequent help to mankind. [For discussion of this paper see p. 1060.]

THE REQUIREMENTS OF A DEPARTMENT OF RADIOLOGY IN A SMALL HOSPITAL*

H. J. ULLMANN, M.D.

SANTA BARBARA, CALIF.

THERE is an old recipe for rabbit pie that begins, "first, catch your rabbit." The first requirement for a department of radiology is to obtain the services of a competent radiologist. It is common practice to equip a department and then look for a director, which is a great mistake. The director should be chosen and given as much latitude as possible in deciding, not only as to type of apparatus, but also organization, personnel and operation of the department, for which he should be held responsible. Where this is not done the directors of a hospital and the staff are bedeviled by the manufacturers, and often are persuaded to put in a more expensive type of machine than required, or a far more complete equipment than is needed. An experienced roentgenologist entering such a laboratory almost invariably finds it necessary to discard or change to a greater or less degree. When he does, the directors are shocked because they have been assured by the makers of the equipment that it is the very latest and best. The director should have the decision, as he must work with the machines and is held responsible for the results.

To obtain a competent director, it is necessary to offer him not only reasonable financial compensation, but satisfactory physical and professional inducements as well. In a small hospital the physical requirements must necessarily vary, not only with the number of beds, but also with the size of the community, the type of work done and the presence or absence of other hospitals in the neighborhood and their facilities. To illustrate, if the hospital is the only one within a reasonably large radius, is doing general work and the staff is a live one, the equipment should

be sufficient to meet any reasonable requirement of roentgen diagnosis. With the present equipment offered by a number of reliable manufacturers, this can be done at an expenditure within the means of any hospital of 75 beds or over. By a reasonable requirement, I do not mean apparatus heavy enough to take stomachs in one-tenth second or chests at 6 ft. in the same or less time. I mean equipment that will turn out diagnostic films of any part of the body, stereoscopically, if desired. It is hardly necessary to add that a fluoroscope for both horizontal and vertical positions is an absolute necessity. If the hospital is in a large community with a completely equipped institution close by or is limited in the kind of work done, the directors must decide, after consulting with their roentgenologist, whether the department should be complete or modified to suit their special conditions. In certain instances arrangement can be made with an institution or private laboratory in the immediate vicinity to take care of special examinations or treatments. One of the most difficult decisions to make is the amount of treatment to be undertaken. The directors of a small hospital, with proper pride in their institution, may want the department to be prepared to treat any patient requiring radiation therapy, considering that the department has failed in its duty if a patient must be sent to another hospital, either at home or elsewhere, for treatment. This is a mistake. To treat all patients needing radiation therapy, and to do it properly, requires an outlay greater than for all the rest of the department. An adequate supply of radium may cost as much as the entire diagnostic equipment, and the addition of a 200,000 volt roentgen

* Presented at the Annual Congress on Medical Education, Medical Licensure and Hospitals, Hospital Departments of Radiology, February 19, 1930.

therapeutic equipment can easily double this. Even more serious is the prescribing and application of the treatment. It is easier to obtain the services of a roentgenologist capable of handling the diagnostic service and even the roentgen therapy than to find one who is also trained in the use of radium. There is no greater tragedy, except incompetent surgery, than ignorant or carelessly used radium, especially when combined with the roentgen-ray. I, not infrequently, see "situation-wanted" advertisements of technicians, who list under experience that they are trained in roentgen therapy. I know of small hospitals where the staff members refer patients to their technicians for a "series of x-ray treatments." Would one of the same staff refer a patient to a nurse for a "course of tuberculin or digitalis therapy?" I doubt it. No treatment should ever be given unless the entire dose, including intervals and all details, be prescribed by a physician who knows what he is prescribing and why.

Of even more importance than the physical are the professional inducements. There is nothing more discouraging to a roentgenologist, especially if he be young, than to be considered by the members of the staff as no more than a high-grade technician. This rarely applies to a large hospital, but not infrequently occurs in the smaller ones, especially if the community is small and is a considerable distance from a large city. One of the first requests a roentgenologist is apt to receive in such circumstances is for "one view of the wrist," "three plates of a barium meal," and "an x-ray diagnosis of the lungs." If he does not make a definite diagnosis of lung tuberculosis with full statement of the degree and probable prognosis, he is considered incompetent. Not long ago I was visiting a young roentgenologist in a small hospital. I was much surprised that, instead of making interpretations of his roentgen findings, he was making positive diagnoses without knowing anything of the patients' histories or physical findings. On being asked how

he could do it, he replied that the staff required definite diagnoses and that he could not retain his position if he did otherwise. He had tried to convince the staff that their attitude was wrong, but was told that the department had been established for the purpose of diagnosis, and diagnosis they would have. No roentgen department can do its duty to its patients or its hospital until the staff will consider its director a colleague, who acts as a consultant when the roentgen ray is used, and that the laboratory is one of the means required to enable them to arrive at a correct diagnosis. The director must be allowed to take such pictures and make such fluoroscopic examinations as he considers necessary to obtain all the information possible with the roentgen ray. Therefore, bills should be rendered for roentgen examinations, not for so many films taken. The director should be limited as to the number taken in any given case. If he is not competent to judge this, he is not competent to be the director. Requisitions for department services should require that an examination be made of such and such a region, and the suspected condition. All other details must be left to the director. This also applies to therapeutics. No requests should be made for "five x-ray treatments of the right breasts," "one x-ray treatment a week to front of the face." They should read "postoperative (or pre) radiation of right breast for carcinoma," or "radiation of right breast for mastitis," "radiation treatment of face for acne." As in diagnosis, the details of technic must be left to the radiologist, and if there are special features, the referring physician should consult with him before treatment is started.

There is a part of the department of radiology that is often overlooked in the large as well as the small hospital, the use of the longer wave radiations. It is common practice to put ultraviolet generators in the physiotherapy department under a technician. This is a dangerous as well as a bad practice and not countenanced by the

American Medical Association. The time allotted to this paper is too short to go into the subject, so this statement will stand without discussion. A physician should be allowed to prescribe the dosage for his patients, if he so desires; but if he does so, he must give all the data, type of reaction desired, etc. and not simply order "quartz lamp, ten minutes, twice a week." Such an order could result in anything from almost no effect, to a severe burn, depending on distance, age of lamp, etc. It is wiser to consult with the director concerning these treatments as in roentgen therapy.

The question of the financial arrangements with the director is often a stumbling block to satisfactory service. In principle, the arrangement should be such that the hospital receives enough from the fees to cover all carrying charges, including the replacement of obsolete equipment. It should not expect to make a handsome profit from the department any more than it would from the operating room. There is usually insufficient work in a small hospital for a full-time man, but whether full-time, or not, the fairest arrangement is a percentage of gross or net income. If either, the hospital percentage should be just sufficient for replacement of obsolete apparatus and additions for a growing

department. Some such arrangement stimulates the director to build up the department and increase his work, both as to quality and quantity.

The equipment of a department by the director at his own expense, and in which, therefore, all fees are necessarily collected by him, becomes, as a rule, essentially unsatisfactory. If he does not satisfy requirements, it is difficult for the hospital to make a change and conversely, it is difficult for him to change if such appears to his best interests. There is one exception, the ownership of radium and deep therapy equipment. In this instance the physician, who will usually confine his practice to radiology, if he is willing to invest such a large sum in equipment, finds it to his advantage to have his high voltage machine in the hospital. It is economically unsound for a small community to have two large equipments operating, one at the physician's private office, and one at the hospital, when there is only enough work to keep one machine running half the time.

There has been no attempt to discuss more than general principles. Each institution must necessarily be an individual problem, but it is believed that these will apply to all. [For discussion of this paper see p. 1060.]

RELATION OF A HOSPITAL DEPARTMENT OF RADIOLOGY TO THE PRIVATE RADIOLOGIST*

L. R. SANTE, M.D.

ST. LOUIS, MO.

IT will be conceded by all that Radiology has become an indispensable aid in the diagnosis and treatment of disease, and that it must be available for the service of patients and aid of the physicians in every well regulated hospital. It is essential therefore that the hospital management make every effort to secure adequate radiological service. While the need for this service is universally understood, there does not seem to be any uniformity of opinion as to just how this is to be brought about. In order to secure the opinion prevailing among radiologists throughout the country a questionnaire was sent to 125 men prominent in this specialty. The information obtained in these questionnaires serves as a basis for the following paper.

A wide variety of arrangements are now in use by various institutions, which seek to provide them with efficient radiological service. These arrangements vary of course with the size and type of institutions which they serve. Some are large enough to require the entire time of a radiologist, others may operate on a part-time basis; some are largely charity institutions, while others may be used entirely for private patients; some may be affiliated with medical schools where teaching of students and internes plays a prominent part in the activities of the department.

It is not within the province of this paper to analyze the requirements of hospital radiological departments, but it is my purpose to point out certain fundamental requirements which are essential to the Radiologist for the successful administration of his department. Well meaning hospital boards who desire to advance radiology as a science would do well to

give their earnest consideration to the manner in which their radiological departments are administered. No radiology department, no matter how elaborately equipped can give adequate service to its clientele or render proper aid to the hospital physicians depending upon it, unless it is in charge of a competent trained radiologist. By competent trained radiologist is meant a graduate physician who has had at least sufficient experience in general medicine to provide an adequate background for his radiological work. His subsequent training in radiological practice should be under some preceptor of acknowledged capability in a large well-regulated laboratory and should be continued until his instructor is convinced that he is capable of assuming individual responsibility. It may be depended upon that in this, as in any other field, his opinion will be valuable in direct proportion to his previous experience. The radiologist should be a man of sufficient experience to render his opinion valuable to the members of the staff with whom he will be called upon to consult. The recent tendency of some institutions to install young men, on small salaries, fresh from their hospital internship without practical medical background or adequate radiological training, as heads of hospital radiological departments to pass their opinions upon matters vital to the welfare of the patient and to consult with established practitioners, is an insult to the intelligence of the physician and an injustice to the patient. This effort by lay hospital boards to reduce the cost of medical care at the expense of the radiologist will be found a dearly purchased economy.

The radiologist should properly be con-

* Presented at The Annual Congress on Medical Education, Medical Licensure and Hospitals, Hospital Departments of Radiology, February 19, 1930.

sidered as a consultant and all of his relations with the medical profession should be considered in the nature of consultations. The same ethical principles which apply to any other medical consultant should apply to him in his relationship with other physicians.

If it is not the opinion of the radiologist that the physician seeks when he sends a patient for examination but merely as x-ray photograph of a certain part, the radiological departments of hospitals may just as well be turned over to lay technicians.

If it is agreed that the radiologist is to be considered a consultant, then he should be given a position on the same footing as the rest of the staff in keeping with the dignity of his position, in order that he may retain their respect and secure their full cooperation. He should be actual director of his department, not director in name only. All department stationery should bear his name as director. He should have charge of all technical procedures and should be consulted in all matters of policy which govern his department. He should have a voice in determining fee schedule for all work done. He should be allowed a percentage of the receipts for the replacement of old equipment, commensurate with the size and income of the department, and should be the sole judge as to when such charges should be made. A certain amount of clinical investigation should be permitted and encouraged. He should, in turn, guarantee competent radiological service at all times, without cost to the hospital management. His compensation should be commensurate with the responsibility of his position and should equal that which he could reasonably expect from similar service in his own private laboratory. The hospital management is entitled to a percentage of the income from the department sufficient to compensate for rental of space occupied, light, heat, janitor service, interest on money invested in apparatus, etc., *but has no reasonable right to expect*

any profit from the work done by the radiologist any more than it is entitled to a portion of the surgeon's, clinician's or any other physician's fees from patients attended in the hospital. One often hears it said that hospitals are not "paying institutions" and that as a result they are entitled to profits from the radiological and pathological work which originates in them to help maintain the institution. The fact that many hospitals operate without endowment or other means of support and still are able to show a profit would seem to indicate bad management of non-profitable institutions. Likewise, even where an institution does not show a profit from its earnings, is this any reason why the radiologist should be singled out to help make up the deficit? Diverting a portion of the radiologist's fee to the general hospital fund is no doubt profitable for the hospital; I can conceive of an even more profitable arrangement by which the hospital would hire surgeons and clinicians on salaries and appropriate a portion of their fees.

The basis of compensation should be on the amount of work done; it matters little whether there is an adjustment salary (one which is changed by agreement from year to year on a basis of work done during the previous year) or on a percentage basis just as long as it represents a reasonable method of compensation for the work performed and *does not exploit the services of the radiologist*. An arbitrary fixed method of remuneration at once places the radiologist on the same basis with all other hospital employees, rendering it impossible for him to maintain the dignity of his position as consultant with the staff. Under these conditions he is bound to be considered more or less of a "glorified interne." No man can rise to his greatest possibilities when he does not feel that he is receiving adequate recognition or a fair return for his work. The percentage method for remuneration is by far the most satisfactory since it makes advancement of the department the common interest of

the institution and radiologist. Under this system the greater the amount of work done, the greater the radiologist's remuneration. This system is most flexible since as the work increases the amount of remuneration increases; the amount of time necessary to perform the work must necessarily increase also; after a time it may be necessary for the radiologist to engage an assistant, but in all circumstances the percentage will adjust the difference. If the institution is large, the amount of work done may be sufficient to justify the radiologist in devoting his entire time to the institution; if it is smaller, a part-time basis may be more satisfactory; in either event the percentage basis overcomes all difficulties. If the radiologist is on a full-time basis, he should be granted a contract for three to five years to assure him of the fruits of his labor after he has built up the department. If he is on a part-time basis and is also engaged in the private practice of radiology in his own office, then a hospital contract, although desirable, is not so essential.

Hospitals are institutions for the care and treatment of sick non-ambulatory patients and are supposed to be operated as an aid to the physician in his work. As such, the hospital radiology department should confine its activities to persons entered in the hospitals as patients who by reason of their infirmities are unable to consult a physician in his office or be treated in their homes. The recent tendency of some hospitals and other lay institutions to establish radiological laboratories for the examination and treatment of outside patients, employing a physician as radiologist on a salary, the institution collecting and retaining the fee, is a pernicious tendency which, if persisted in, most certainly will result in the ultimate exclusion of physicians from radiology as a specialty. If this procedure were carried out in all other departments it would place the practice of medicine in the hands of lay organizations and establish a form of contract practice which would

stifle the progress of medicine for at least a generation. It is most important that institutions which profess to operate for the public good should not enter into open, and in some cases ruinous, competition with the laboratories of private radiologists. Operating as tax-free, charitable organizations, often exempt from liability, with relatively low overhead expenses owing to their locations in outlying districts, their ability to engage in collective purchasing and in advertising, their low cost of technical help, they are in a position to cut prices for radiological service to such an extent that no private radiologist can long maintain his position. They are subjects of charitable bequests and often operate under large endowments donated by wealthy individuals. This is almost the unanimous opinion of all radiologists consulted in the questionnaire; the dissenting members were all employees of large clinics. Definite instances are described in the answers to the questionnaires where hospitals operating x-ray laboratories for the service of outside patients have deliberately reduced the price of radiographic examination below cost, making up their deficits from the community fund, actually forcing local radiologists out of business. If only well meaning but misguided hospital boards could be made to see the throttling effect which such methods will ultimately have on the advancement of radiology as a science, they will see that in their zeal to provide the public with cheaper service, they are condemning them to inferior work. Yet I am advised that certain physicians, in some instances former officers of the American Medical Association, posing as hospital experts, propose the installation of this system to hospital managements whose institutions they are employed to survey.

What can be done to remedy these evils?

1. Choose as radiologist in charge of hospital radiology departments men whose clinical background and radiological experience measure up at least in some degree

with that of the staff members who will seek their services.

2. Establish the radiologist in full control of his department without intervention of hospital boards or staff members; permit him to make all charges and collect all fees. The fee schedule for the hospital should be the same as that prevailing in private laboratories of the community, so that if he is a full-time man, he will not enter into unjust competition with his fellow private radiologist; if he is a part-time man, he will not find that he is entering into competition with himself. It should be equally to his advantage to examine a patient in the hospital or in his private office.

3. Treat the radiologist as a medical consultant. The measures already recommended will go far towards maintaining him on this plane.

4. Assure him adequate and just return for his labor. Any attempt to divert a portion of his fee to the general hospital fund constitutes nothing short of fee splitting, if he is on a percentage basis; or contract practice, if he is on a fixed salary, and such a plan if applied to all other branches of medical practice will soon result in passing the control of medical science into the hands of lay organizations.

5. Hospital radiology departments should restrict their services to patients confined to the hospital, and should not solicit outside patients, thus establishing themselves in open unjust competition

with the radiologist who maintains a private office.

I realize very well that it is impossible for anyone to prescribe the conditions under which a man shall or shall not work, and that it is impractical for this committee to specify the attitude which shall be assumed by hospital boards towards their radiologists. I feel sure that these conditions which mar the relationship between the private radiologist and the hospital management have merely been introduced by misguided hospital boards, in an effort to reduce the cost of hospital care, without any due deliberation as to the ultimate effect which they will have on the science of radiology.

The following recommendations are submitted for the committee's consideration.

1. That, only well qualified trained radiologist should be placed in hospital department of radiology;

2. That, once appointed he should be given absolute control of his department;

3. That, he should be considered in all matters as a medical consultant;

4. That, he should be entitled to the fruits of his labor; that it is inadvisable and contrary to the principles of medical ethics for the hospital management to retain a portion of his fee;

5. That, the practice of hospital departments of radiology in entering into unfair competition with radiologists who maintain offices is unjust and should be discouraged as being detrimental to the progress of radiology.

DISCUSSION OF PAPERS BY DRS. CASE, BUTLER, ULLMANN AND SANTE*

M. J. HUBENY, M.D.

CHICAGO, ILLINOIS

THE subjects presented in this symposium were thoroughly covered and since evaluation is difficult, a discussion would be inexhaustible and chiefly philosophical in nature. However, it is apparent that the basic thought revolves around institutional activities for obvious reasons. Firstly, medicine has changed from an "eleemosynary" activity to a commercial enterprise, meaning that it is a method of gaining a livelihood in which there is an exchange of fair values. Naturally all values are ever-changing and require frequent readjustments. Secondly, because medicine is so comprehensive, specialization becomes necessary. Thirdly, instruments of precision are necessary, entailing a large investment and requiring cubic area for housing. To make a competent service purchasable for the average person, centralization and quantity production are necessary.

The hospital is undergoing a rapid change: the original purpose was to render therapeutic service, but now we have added to this a diagnostic service as well. This evolution is proper and will become more apparent and needful as time goes on.

Institutional medicine will be the final solution for the present chaotic and uneconomic situation. We must sense this situation and help solve it or lay people will do it for us. I firmly believe that physicians are well able to handle their own affairs.

It seems that we will have variants which will tend to adapt themselves to certain environments and localities. There will be three principal classes: (1) institutions supported by taxation, (2) institutions supported by private endowments, (3) those owned and directed by physicians or physicians and laymen.

Institutions will vary in the quality of performance. Large cities with tremendous wealth will be able to have keystone institutions, with the most approved housing and apparatus and a personnel of supermen; they will be able to render the finest service. Naturally, they

will be the pace-makers, and as we are living in the most highly competitive era, the old axiom of survival of the fittest will still prevail for the best interests of all concerned.

Many abuses are practiced and, sadly, the roentgenologist, who has fitted himself, medically and specially, is not accorded the recognition that he merits and justly craves.

It is true that the x-ray apparatus is an instrument of precision and lends itself admirably to greater efficiency. Of course the novice knows little or nothing about its proper use. The general diagnostician pretends to know something about it and really, he becomes more efficient with the apparatus than without it. The specialist naturally becomes very proficient.

Many hospitals engage a radiologist for a low compensation and use his efforts as a source of revenue. This is hardly fair and the abuse is lamentable. However, it is rapidly becoming extinct because the fact is recognized that it is just as impossible to get a highly competent radiologist for little compensation as it would be to get a highly competent surgeon for little compensation. You can buy service, but you cannot buy brains. In other words, an inferior institution, with an inferior service, with inferior compensation, is going to handle the inferior individual of low mentality and low financial depletion.

We have a division of labor. We have the development of the technician. It has been mentioned that we are occasionally considered glorified technicians. I do not think we have to worry about that. Ultimately, the problem will solve itself, in a measure by continual conflicts or, better still, by courtesy and performance. But, we do not have to consider ourselves inferior because we have technicians.

In reality, the technician occupies the same relationship to the radiologist that the surgical nurse bears to the surgeon, or the obstetrical nurse bears to the obstetrician.

I am sure that we all know of instances in which certain obstetrical nurses would be

*Presented at The Annual Congress on Medical Education, Medical Licensure and Hospitals, Hospital Departments of Radiology, February 19, 1930.

better able to deliver a baby than some obstetricians, and quite a number of surgical nurses would be better able to do certain laparotomies than some surgeons. However, as a common practice it would not be condoned and rightly so. The pernicious practice of sending patients to lay persons for radiological service is reprehensible and subversive to the best interests of the patient, and should be discouraged and discontinued.

I think we have very many hopeful signs. I am not quite so despondent. Radiologists are getting a lot of recognition here and there. We were fortunate as medical men in getting a section in the American Medical Association which we all sought for many years, which immediately gave us medical recognition. As

one looks over the list I have here, compiled by the American Medical Association (it is under the caption of Hospitals Approved for Residencies in Specialties), it is interesting to note that we have residencies in universities. I mean radiological residencies in universities, in municipal institutions, city, municipal, state and national in character, then we have the private hospitals such as the Metropolitan Insurance Company, various denominational hospitals and teaching schools and lastly, many private institutions, for instance, the Ford Hospital. All of these, if you look over this list, are high class institutions. I think from the very fact that they sense the situation properly, the final analysis will be made in conformity with the high ideals that radiologists have striven to attain.

REDUCTION OF SIMPLE FRACTURES OF THE EXTREMITIES UNDER LOCAL ANESTHESIA^{*}

JACOB M. MORA, M.D., AND DAVID A. WILLIS, M.D.

CHICAGO, ILL.

THE occasion frequently arises when it is considered hazardous to administer a general anesthetic for the anesthesia was that by Conway¹ in 1885. He reported 3 cases of Colles' fracture and one of posterior dislocation of both bones

FIG. 1. Colles' fracture before reduction.

FIG. 2. Colles' fracture after reduction, using 5 c.c of 1 per cent novocaine solution.

reduction of a simple fracture of an extremity. Several such conditions come readily to mind: senility, advanced cardiac and renal disease, hypertension, and pulmonary lesions. With the great increase in motor accidents, one not infrequently encounters concomitant fracture of the skull and one of the extremities, for the reduction of which general anesthesia is contraindicated. It is in such situations that local infiltration anesthesia is of value.

It is a curious thing that a procedure which originated in America should have been developed to such a high degree abroad. It is a matter of record that the first report dealing with reduction of fractures of the extremities with local

at the elbow satisfactorily reduced under local anesthesia. Reclus² in 1903 made use of the method to transport in comfort a patient with a fractured femur, and found that thirty minutes later the anesthesia was sufficient to permit reduction of the fracture. Sporadic but significant reports subsequently appeared, indicating the value of the method (Lerda, Quenu, Dollinger, Braun, Cumston, Fulton, Hagenbach, Frostell, Cohen, Rice¹⁻¹²). It is only within the past few years that the method has come to be used to any extent.

The advantages of local anesthesia are obvious. In addition to its value where general anesthesia is contraindicated, it may be advantageously used for other

^{*} From the Surgical Service of Dr. H. M. Richter. Submitted for publication March 27, 1930.

purposes. For example, a fracture may be locally anesthetized and the patient then moved to the fluoroscopic room where

FIG. 3. Fracture of surgical neck of humerus before reduction.

reduction may be accomplished leisurely and without the danger associated with the use of inhalation anesthetics. Again,

FIG. 4. Fracture of surgical neck of humerus after reduction, using 15 c.c. of 1 per cent novocaine solution.

should the reduction not be satisfactory, the extremity may subsequently be re-manipulated with local anesthesia until proper reduction is accomplished.

The contraindications to its use are compound fractures, infected or traumatized skin, and infection elsewhere in the extremity.

Theoretically, there exists the danger of introducing infection from without. Practically, however, this is a negligible factor.

FIG. 5. Fracture of femoral neck before reduction.

No cases have been recorded where infection followed local infiltration anesthesia, and with scrupulous care it may be avoided.

The method consists of the injection of the local anesthetic directly into the site of

FIG. 6. Fracture of femoral neck after reduction, using 15 c.c. of 1 per cent novocaine solution.

fracture. We have been using a 1 per cent solution of novocaine with adrenalin (1 minim to the ounce). Under sterile pre-

cautions, a small wheal is made in the skin, and with another longer needle the solution is injected between and around the fragments. One knows when the fractured area is reached by observing the washed out, faded blood that wells up in the syringe and which is readily distinguished from the blood that is drawn up in the syringe if a blood vessel is punctured. Five to 60 or 70 c.c. may be injected depending on the type of fracture and the size and condition of the patient. We have found small amounts quite satisfactory. Anesthesia is usually complete in from ten to thirty minutes. It is astonishing to see the remarkable change produced by the local anesthesia: patients who a short time before would not even allow one to touch the affected extremity soon permit every kind of manipulation, without uttering a sound.

The following cases are illustrative:

CASE I. Mrs. F. L., aged seventy-five, was admitted to the hospital with a fracture of the surgical neck of the left humerus. Satisfactory and painless reduction was accomplished with 15 c.c. of novocaine (1 per cent).

CASE II. Mrs. H. K. aged ninety-three, was admitted with a fracture of the surgical neck of the left humerus. In this case also, the injection of 15 c.c. of solution sufficed to permit manipulation and reduction of the fracture.

CASE III. Mrs. S., aged sixty-three, a diabetic with a systolic blood pressure over 200 sustained a fracture of the surgical neck of the left humerus. Reduction was easily accomplished after the injection of 15 c.c. of novocaine.

CASE IV. Mrs. I. G., aged fifty-eight, sustained an intertrochanteric fracture of the left femur. An almost perfect reduction followed the injection of 15 c.c. of novocaine.

CASE V. Mrs. A. S., aged fifty, was admitted with a Colles' fracture (left). The fragments were satisfactorily apposed after the injection of 5 c.c. of solution.

CASE VI. Mrs. L., aged sixty-five, sustained a right Colles' fracture, which was satisfactorily reduced with 5 c.c. of novocaine.

SUMMARY

Attention is directed to the value of local infiltration anesthesia, as a simple, safe, practical procedure in the reduction of simple fractures of the extremities.

HERNIA OF THE SMALL INTESTINES

INTO THE LESSER PERITONEAL CAVITY

REPORT OF A CASE*

BYRON H. JACKSON, M.D.

SCRANTON, PA.

AT necropsy and at operation the small bowels have occasionally been found in the lesser peritoneal cavity, condition. Lombard¹ in 1923 reported 29 cases, in 11 of which there were digestive disturbances of varying degrees. Case

FIG. 1. Shows stomach ten minutes after opaque meal. Notice at this time small bowel is shown only on left side.

FIG. 2. Three hours after ingestion, stomach nearly empty. All small bowels are on left side.

having slipped through the foramen of Winslow. This statement may be verified by turning to the anatomy of the peritoneal cavities, in which the foramen of Winslow is described. The great rarity of this hernia is due to the protected position of the foramen and the overlying liver. Pfanner¹ and Stauning in 1921 made a correct roentgenological diagnosis of this

¹ Quoted from CASE and UPSON, *J. A. M. A.*, 87: 891-897, 1926.

and Upson,¹ in 1926, gave the roentgenological aspects of various types of internal hernias, among which was that of the small bowel into the lesser peritoneal cavity. Since hearing this latter paper, the author of this report has been on the lookout for these various conditions, and his vigilance has been rewarded by finding, during a routine hospital examination, the following case of hernia of the small bowel into the lesser peritoneal cavity.

* Submitted for publication April 18, 1930.

CASE REPORT

A. W. B., a well developed, healthy appearing male, age forty-eight, 5 ft. 7 in. in height;

X-ray Findings: Stomach and duodenal bulb apparently normal. There is hyperperistalsis. Figure 1 shows the stomach ten minutes

FIG. 3. Four hours after ingestion, slight residue in stomach, small bowel still on left. Note slight dilatation of small bowel.

FIG. 4. Five-hour film, same condition.

occupation, insurance salesman. Chief complaint indigestion, with intermittent pain in the upper abdomen. Has been having frequent attacks of pain in the upper abdomen over a period of fifteen or twenty years. Pain is sharp at times, of a colicky character; at other times it is simply a distressed feeling. Pain comes on one to two hours after meals, and at night between twelve and one o'clock. Heartburn at times. Relief has been obtained by flexing right leg on abdomen and bending over. Hot water and soda sometimes give relief. Laxative occasionally relieves. Pain aggravated by indiscretions of diet, acid foods, etc. Short periods of complete relief were experienced, and then long periods of distress. Vomiting an occasional symptom. No blood in vomitus or stools; no loss of weight. Palpation of the abdomen elicits slight tenderness in the epigastrium. No rigidity.

after opaque meal. Notice at this time the small bowel is shown only on the left side. Figure 2, three hours after ingestion, shows the stomach nearly empty. All the small bowels are on the left side. Figure 3, four hours after ingestion, shows a slight residue remaining in the stomach, with the small bowel still on left. Note the slight dilatation of the small bowel. Figure 4, five-hour film, shows the same condition. In Figure 5, the six-hour film, note the opaque material in the small bowel reaching up to pass through the foramen. Figure 6, seven-hour film, shows the small bowel partially within and partially without the lesser peritoneal cavity. Note the angulation of the ileum as it passes through the foramen. In this roentgenogram the cecum is already filling.

At operation the small bowel was found in the larger peritoneal cavity. The foramen of Winslow admitted three fingers. The foramen

was closed by suturing the layers of the peritoneum. One year after operation, roentgenograms of the stomach and small bowel were

well for two and one-half years, and has had no recurrence of symptoms.

The author is indebted to Dr. Carl Hosier

FIG. 5. Six-hour film. Note the opaque material in the small bowel reaching up to pass through foramen.

FIG. 6. Seven-hour film. Small bowel partially within and partially without the lesser peritoneal cavity. Note angulation of ileum as it passes through foramen. In this picture cecum is already filling.

normal and there was no evidence of displaced small intestines. The patient has been perfectly

for the history of this case and for permission to report it.

· CASE REPORTS ·

CARCINOMA OF THE BLADDER

URETEROSIGMOIDAL IMPLANTATION, TOTAL CYSTECTOMY*

PAUL W. ASCHNER, M.D.

NEW YORK

THE SUBJECT of this presentation is a man sixty-two years old who was referred for frequency, dysuria and hematuria by his family physician on January 25, 1929. The symptoms were of three months duration and had grown progressively worse so that he was now voiding every half to one hour by day, and every twenty to thirty minutes by night. The urine was grossly bloody and contained much pus; residual, two ounces. Per rectum the prostate was symmetrically enlarged to three times the normal size. Roentgen examination of the genitourinary field showed a few phleboliths, no calculi and no evidence of metastatic lesions of the lumbar spine or pelvic bones.

Cystoscopic examination disclosed intra-urethral enlargement of the lateral lobes of the prostate. On the anterior wall of the bladder extending downward to the vesical neck and laterally along the left lateral wall to the left ureteral orifice was a papillary partly necrotic growth evidently malignant in nature. Specimens removed for histological study proved it to be a papillary carcinoma with a tendency to squamous metaplasia.

In view of the extent of the lesion, its location and nature, total cystectomy with removal of the prostate and seminal vesicles was advised. Having observed the miserable existence of patients upon whom this procedure had been carried out in one step, the ureters being brought out on the abdominal wall and tubes carried in them for the rest of the patient's invalided existence, it was deemed preferable to precede the cystectomy by the simultaneous implantation of both ureters into the sigmoid as devised by Coffey. Since the patient was spare of build, he seemed a particularly favorable subject for this procedure.

The man refused operation at this time and it was not until August 19, 1929 that he

agreed to undergo it and entered the hospital. The blood urica was 18 mg. per 100 c.c. On August 23 the intestinal tract having been prepared by catharsis and enemata, the first step was carried out. As I found it impossible to pass a sigmoidoscope more than 15 cm. the introduction of a packing into the sigmoid had to be dispensed with. Spinal anesthesia, 0.12 neocaine, was employed, supplemented later by gas oxygen and ether. A liberal median infraumbilical laparotomy was performed. The ureters were exposed by incising the posterior parietal peritoneum over them. They were both dilated, measuring fully a centimeter in diameter, thin-walled and tortuous. After being traced downward almost to their vesical insertion, they were divided as low down as possible, the vesical ends being ligated with chromic catgut. The upper ends were slit for about 2 cm. and No. 12 catheters introduced toward the kidneys for a distance of about 12 cm. At this point the slit ureters were secured to small rubber cuffs with which the catheters were armed. The typical submucosal implantation described by Coffey was now carried out. The free ends of the catheters were pushed downward through a small mucosal incision until an assistant could withdraw them from the rectum. Traction was then exerted upon the catheters until the rubber cuffs had passed into the lumen of the bowel. The ureters were then buried in the sigmoidal wall by the necessary chromic catgut sutures to approximate the incised serous, muscular and submucosal coats. A Lembert linen stitch then completed the anastomosis.

The ureteral beds were then closed with fine catgut and as the bowel was approached the sites of implantation were carefully extraperitonealized. The abdomen was closed in layers without drainage. A slight technical error was

* From the Urological Service of the Brownsville and East New York Hospital. Read before Section of Genito-Urinary Surgery, N. Y. Academy of Medicine, October 16, 1929.

made in that the right ureter was implanted lower down than the left; but this did not inconvenience me to any extent.

The postoperative course of the patient was characterized for five days by extreme abdominal distention for which at first we could employ only turpentine stupes. On the seventh day calomel and a saline produced good evacuation and complete relief. The ureteral catheters drained copiously and without interruption. The specimens showed from the very first some leucocytes on both sides.

To prevent incrustation, daily instillation with acriflavine was employed. On the tenth day the catheters came away spontaneously; very small sloughs were adherent to the rubber cuffs. I present the catheters for your inspection. On the tenth day the temperature rose to 101° and there was considerable suprapubic pain and tenderness. A catheter introduced into the bladder yielded four ounces of thick foul pus and blood. Thereafter the bladder was emptied and irrigated daily until clear. This procedure eliminated the fever and local symptoms. On the twelfth day, the wound having healed by primary union, the patient was allowed out of bed. He had complete control of the rectum, emptying it of urine and feces five or six times a day.

On September 9, 1929, seventeen days after the first step, the cystectomy was performed. The bladder was thoroughly irrigated and emptied. Spinal anesthesia was again administered. The original incision was reopened down to the bladder and peritoneum. The rectus muscles were partly cut across near the symphysis to permit of better exposure. With considerable difficulty a plane of cleavage was found between the bladder and the peritoneum laterally. When we attempted to isolate and free the fundus, the peritoneal cavity was entered and the sigmoid flexure was found adherent to the peritoneum covering the posterior wall of the bladder. By careful sharp and blunt dissection the separation of the peritoneum from the bladder was accomplished down to the region of the prostate and vesicles. The bladder was now mobilized by dividing the lateral ligaments between clamps as far out as possible. The vasa deferentia were ligated and divided and the seminal vesicles exposed. The fascia of Denonvilliers was incised and the prostate freed bluntly, posteriorly and laterally. By dividing the puboprostatic ligaments, I freed the entire mass to be removed,

except for its attachment to the membranous urethra. This attachment was severed with a curved scissors and the specimen removed in

FIG. 1. Bladder, prostate and seminal vesicles removed as a unit. Specimen opened along midline anteriorly. Large papillary carcinoma infiltrating muscularis, involving trigone and vesicle neck. Hypertrophied bladder due to obstruction of the latter.

one piece—bladder, prostate and seminal vesicles. Considerable venous bleeding occurred from the divided urethra but was controlled by packing and the pressure of a Deaver retractor. After applying hemostatic sutures, we removed the clamps on the lateral ligaments.

The peritoneal rent was now carefully repaired. The huge cavity left by the radical resection was drained with a Mickulicz tampon of rubber dam and gauze. This was lead out above the symphysis and the rest of the wound closed. A rectal tube was inserted.

The patient's convalescence was remarkably smooth. There was not the least interruption in the renal function, the bowel emptying itself at first through the rectal tube, then naturally. On the fourth day the packings were removed and a tube inserted. There was a profuse discharge of thin purulent foul fluid which strongly suggested urinary leakage. Methylene blue given by mouth appeared in both the drainage and the rectal discharges. The urea content of fluid from the wound was

0.6 per cent. Indigo-carmin administered intravenously subsequently failed to appear in it, although promptly appearing from the rectum. With discharge of several sloughs the drainage from the wound became much less. It is possible that a pin point opening in the rectum was made in dissecting out the prostate. No fecal matter ever came through it and the urea content may have been due to the pus alone. There is still some thin serous odorless discharge; but I attribute this to the large raw surfaces which still remain unobliterated.

The specimen consists of the bladder, prostate and seminal vesicles removed as a unit. It has been opened in the mid-line anteriorly. (Fig. 1.) The bladder wall is markedly hypertrophied. A large sessile papillary growth involves the left ureteral orifice, the paratrifurcal region, the left lateral wall and the anterior wall of the bladder. Only the right half of the trigone is free. Superiorly, the growth extends about halfway to the apex of the bladder on the left side. Inferiorly, it extends well down to the bladder neck. On section the growth is found to be a papillary carcinoma with tendency to squamous metaplasia. It shows invasion of the bladder wall.

DISCUSSION

DR. B. S. BARRINGER: I have never been able to admire this operation but I cannot but admire Dr. Aschner's admirable performance of it. It is a beautiful technic, and that is what lures us on; and when you do what he has done you have accomplished a beautiful technic. There is no need of my going further, but I believe it will never be a popular operation; the mortality is high. I believe about 50 per cent.

I would like to ask Dr. Aschner how much induration of the bladder there was. Of course when we saw the picture it had infiltrated the bladder wall; but that was not a great deal. It struck me that the case might have been treated with radium with just as much chance of cure and with a 3 or 4 per cent mortality.

Dr. Coffey, when I was in Boston, radiated the tumors very severely, and before the ultimate effect of the radiation was attained, i.e. in four to six weeks, he took the tumor out. That was a very interesting way to do. He evidently had opened the bladder and radiated the tumors.

DR. ASCHNER, *closing*: Dr. Barringer says the mortality of this operation is about 50 per cent; but that is based on statistics of ureteral implantation going back for many years when the technic was not the same. Catheters were not used and rarely were both ureters transplanted at one time. In 1923, Fedoroff of Petrograd, however, reported five cases of bilateral transplantation only one of which was lost. Of the four in which the cystectomy was carried out, one remained well without recurrence six years after operation. Lower reported two successful cases in which the ureters were transplanted separately, the cystectomy being performed as the third step.

The risk of mortality in the two-stage radical operation is not from the cystectomy, but from the ureteral transplantation. Under modern conditions and technic, I believe this mortality is between 10 and 15 per cent. The mortality of the one-stage operation of cystectomy bringing the ureters out upon the skin, is at least equally high. The incidence, moreover, of pyelonephritis, calculus, stricture of the ureter, etc., after such operation, together with the discomforts and the amount of care necessary, make preferable the procedure used in the patient presented tonight.

I have employed all the means, both surgical methods and physical agents, in vogue, for the treatment of malignant vesical tumors; but this man has had a smoother, more comfortable convalescence than those upon whom the less radical procedures have been practiced. While nothing may be said as to the permanence of the result, I feel that certain types of bladder carcinoma can be treated rationally only this way.

FOREIGN BODIES IN OS CALCIS*

G. H. V. HUNTER, M.D., F.A.C.S.

BROOKLYN, N. Y.

FROM time to time we read in the lay press of the migration of a foreign body, such as a needle, throughout the human body. This is a report of a case of a piece of nail piercing the os calcis in childhood, becoming firmly surrounded by solid bone and giving no symptoms for twelve years.

CASE HISTORY

While romping on the beach, a child, twelve years old, cut his foot. It bled a little and the foot was examined by a doctor, who said it was a small punctured wound. He treated it aseptically and the wound healed in a few days. The boy thought no more about it until years later when he commenced to have a dull aching pain in the heel. He sought medical advice and the roentgen ray as here shown revealed the cause of the trouble.

Examination showed a well-developed man of twenty-four years. No evidence of injury was found on the foot and tenderness was elicited on pressure. I advised an operation for removal of the foreign body and he was admitted to the hospital.

Operation: I was somewhat at a loss as to the method of approach as there seemed to be at least a half inch of solid bone covering the nail and I did not like the idea of ruthlessly chiselling away bone to reach it. I solved the difficulty by using a trephine and took out a plug of bone from the outer side of the os calcis, at the site of the nail shadow in the roentgen ray. At the depth of $\frac{3}{4}$ inch I struck the nail. I removed the plug of bone, placing

it in warm saline. I then, with considerable difficulty, extricated the piece of nail through the trephine opening and curetted away a

FIG. 1. Lateral view of foot showing foreign body within os calcis completely surrounded by solid bone.

little rusty bone. There was no sign of any infection and I irrigated the cavity with saline and replaced the plug of bone which healed perfectly. The result of the operation was a happy one. The patient left the hospital in a few days, walked in a slipper in two weeks and resumed his work in one month. The foreign body proved to be a piece of nail with the head and point broken off. It measured $\frac{7}{8}$ in. long, $\frac{1}{8}$ in. wide, and $\frac{1}{16}$ inch thick.

RESECTION & ANASTOMOSIS OF THE IMPERVIOUS URETHRA*

WILLIAM NEILL, JR., M.D.

BALTIMORE, MD.

IN MY clinic at the Cambridge-Maryland Hospital I am constantly called upon to solve the many and varied problems in general surgery. Prompted by Dr. H. H. Young's article,¹ on the treatment of complete rupture of the posterior arethra, I submit a complete report of three patients with lesions in the bulbous urethra anterior to the triangular ligament, two of complete rupture from a fall astride some object, one recent, and the other four and one-half months old and after previous operation. The third, similarly located and impermeable, was the sequel to an old gonorrheal infection and resistant to previous attempts at dilatation.

The lesions found in rupture of the urethra vary from slight lacerations all the way to a complete division, complicated at times with an extensive fracture of the pelvis with urinary or fecal extravasation. Extreme cases are seen following crushing injuries rather than a fall as in two of my patients. In view of the importance of the departure from the routine methods, I shall report them separately and in detail.

CASE I. White, aged thirty-eight, married; occupation, railroad fireman, on May 4, 1926 slipped into the water tank of his tender and fell several feet on to a submerged pipe, sustaining a severe and painful perineal injury with immediate severe pain, inability to void and bleeding from the urethra. Seen two hours later; excellent general condition, hemoglobin was 80 per cent, abdomen negative, the external genitalia not affected but a distinct bulging in the perineum. Per rectum a normal prostate was felt and definite compression of the rectum by a soft mass extending up to the base of the bladder. A catheter passed into the urethra reached the region of the membranous urethra

and evacuated a moderate amount of blood; a finger in the rectum detected the catheter free in a cavity in front.

Diagnosis: complete rupture of the urethra with extravasation of blood. An x-ray examination of the pelvis disclosed a transverse fracture of the right descending pubic ramus in situ.

Operation: A longitudinal incision in the perineum opened into a large hematoma; when this was evacuated an actively spurting artery was seen. This and all lesser bleeding points were controlled by plain catgut ligature. Investigation with a sound per urethrum revealed the bulbous urethra completely severed just in front of the membranous urethra and the triangular ligament. The posterior end could not be located in the bruised and bloody field and, as I did not feel a suprapubic retrograde catheterization advisable at the time, the skin was united loosely with catgut around a gauze drain. When the patient recovered from the anesthetic, voiding was normal through the perineal wound, no urine passing from the meatus; this continued until June 9, 1926, when healing was complete except up to a small urinary sinus. On this date the second operation was done to anastomose the severed urethra. A rubber catheter was passed into the bladder through the perineal sinus and the healed incision reopened and a metal sound passed through the meatus which reached to within $2\frac{1}{2}$ cm. from the posterior urethral opening. The completely closed anterior end was opened on the tip of a sound and freed with sufficient paraurethral tissue to assure circulation and thoroughly mobilized. The posterior segment was likewise mobilized. A No. 24 F. soft rubber catheter was introduced anteriorly to the perineal opening, when the original catheter was removed, and passed on into the bladder. Around the catheter a transverse end-to-end anastomosis was done with interrupted No. 0 twenty-day catgut sutures. Additional sutures of plain fine catgut were placed through the fibrinous and muscle tissue to reinforce the

¹Young, H. H. *Trans. Am. Assoc. G.-U. Surg.*, 21: 1928.

* From the Howard A. Kelly Hospital. Submitted for publication December 3, 1929.

first line of closure. A small gauze drain was placed to the line of anastomosis, and the closure completed with plain catgut. The convalescence was normal; the catheter, remaining in place without any leakage, was removed on the tenth day. Voiding was normal and in two weeks the incision was healed. The fracture gave no trouble. Dilatations were carried out June 23, July 2 and 9, September 16, December 1 and January 24, 1927. July, 1927, sounds revealed no stricture and erections were normal. He has remained free from any sequelae.

CASE II. White, aged sixty, married. Occupation: carpenter. While working September 1, 1926 fell astride a saw horse and sustained a severe blow on the perineum. An operation done the same day for a ruptured urethra through a suprapubic and an inverted U incision in the perineum was unsuccessful, and the urine drained suprapubically and through two perineal fistulae. Perineal abscesses developed from time to time, either rupturing spontaneously, or calling for an incision. There was always a discharge of pus demanding a pad. For a short time a small amount of urine passed the meatus, but none for two months up to the time I first saw him on January 19, 1927, when he came through the advice of the first patient. Examination negative, outside the local condition. The healed suprapubic scar drained a little urine through its lower angle. There were two small discharging sinuses in the perineum. He voided urine through both voluntarily, and the entire region was densely scarred. External genitalia were normal, prostate was diffusely hypertrophied, without symptoms. Rectal examination otherwise negative. Filiform bougies introduced into the perineal sinuses failed to enter the bladder and a sound passed through the meatus only reached the membranous urethra, the tip just being palpable per rectum through the dense scar tissue.

Diagnosis: complete traumatic rupture of the bulbous urethra with marked cicatrix and water-pot perineum.

Operation on date of examination under ether anesthesia. The anterior urethra and both perineal sinuses were injected with methylene blue. A metal sound was passed through the anterior urethra to the point of obstruction and a second through the suprapubic fistula

into the bladder out through the prostatic urethra, the tip extending through the membranous urethra. A median incision was made in the perineum and both sinuses dissected out under the guidance of the methylene blue, as they led by separate tracks to the tip of the sound in the membranous urethra just outside of the triangular ligament. A large amount of scar tissue was dissected away, clearly exposing both sounds and completely destroying a gap of 3 cm. of the urethra. The severed ends were freely mobilized and all fibrous thickening removed out into the normal surroundings. A No. 24 F. soft rubber catheter was passed into the bladder through the posterior segment as the sound was removed and the distal end threaded on to the tip of the anterior sound and withdrawn out through the anterior urethra. An end-to-end transverse anastomosis was done around the catheter with interrupted No. 1 twenty-day catgut sutures, reinforced by additional sutures of plain catgut. The skin was loosely united with black silk and a plain gauze drain left inserted at the posterior angle. Convalescence normal, healing without leakage or extravasation. The suprapubic incision healed spontaneously. The catheter was removed on the twelfth day and sounds to No. 20 F. passed on the fourteenth day. When the patient was seen in two months voiding was normal and I was able to dilate to a No. 28 F. He was well in July, 1927 when sounds were passed; a further recent report states that he is well.

CASE III. Differing from the preceding was the case of a patient with an impermeable stricture from an old gonorrheal infection. As the operative procedure was somewhat similar, I include it here. The patient, white, aged fifty-one, married, was by occupation a water-man. As a youth he contracted gonorrhea, and for twenty years had attacks of dysuria lasting several weeks; at no time was he able to void normally. This gradually increased and no prolonged relief was experienced from dilatations. In March, 1929 an operation was done for hemorrhoids and the stricture unsuccessfully dilated and since then, particularly for the past three weeks, has been in constant pain, emptying the bladder most of the past week involuntarily by dribbling. Attempts to catheterize have failed. I first saw him September 12, 1929, in great pain,

with the bladder extending halfway to the umbilicus with an involuntary dribbling of ammoniacal urine. A sound refused to go beyond the region of the triangular ligament; the obstruction was also impermeable to filiform bougies. The prostate was normal and above it lay the tense, distended bladder. Rather than do a cystostomy I decided to resect the stricture from below. Methylene blue was injected anteriorly and milked towards the bladder. A median perineal incision was made and the tissues cut down to a sound passed to the obstruction. The urethra was dissected free over the sound and opened on its tip. It was markedly thickened and the lumen tortuous and threadlike, a fact clearly demonstrated by the methylene blue. The stained tract was followed up to the normal urethra just in front of the triangular ligament. The entire segment of the urethra (2.5 cm.) was excised with all enveloping scar tissues. A No. 22 F. soft rubber catheter was then introduced into the bladder, evacuating 1200 c.c. of foul urine. The distal end of the catheter was then threaded over the tip of the sound and drawn out through the meatus. With moderate tension the ends were joined transversely about the catheter with interrupted No. 1 twenty-day catgut sutures, reinforced by plain catgut sutures, and the skin closed with interrupted sutures, leaving a small cigarette drain up to the anastomosis. Convalescence normal; no leakage or extravasation of urine until the catheter was removed on the seventh day as the patient began voiding around it, with some leakage through the perineum. Voiding continued normal and the perineal leakage grew less and ceased at the end of the fourth week when the healing was complete. At the end of the second week I passed a small sound into the bladder. A No. 28 F. easily passed in the fifth week and voiding was normal. He was seen

and dilated October 30th; subsequent dilatations will be continued.

CASE IV. A fourth patient was operated upon at the Church Home and Infirmary, Baltimore, in 1915. Since a portion of the history is lost, a detailed report cannot be given. An employee of a timber company in North Carolina fell while at work, straddling an object and sustained a severe blow on the perineum, followed by bleeding from the urethra. He remained in a local hospital for three weeks with a retention catheter; following its removal he found voiding difficult at first, gradually growing worse. Attempts to dilate gave no definite relief. When I saw him approximately six months after the injury, I found the bulbous urethra markedly indurated, and a sound stopped at this point. After consultation with the late Dr. J. T. Geraghty, instead of an internal urethrotomy, an open operation was carried out as described in Case III; this was followed by complete relief. Subsequent dilatations were carried out, the patient remaining perfectly well until I lost track of him five years later.

CONCLUSIONS

1. Accurate knowledge of the regional anatomy is a prime requisite.
2. Preliminary injection of methylene blue is of great assistance, outlining the distorted urethra and any diverticula for the subsequent operation.
3. Sharp dissection, delicate instruments and fine sutures with careful manipulation insure the union of the approximated tissues.
4. Some follow-up dilatations of the urethra must be carried out later to obviate any stricture in the tract.

INFLAMMATORY CARCINOMA OF THE BREAST*

CHARLES M. FOX, M.D.

SAN DIEGO, CALIF.

I AM reporting these cases as, contrary to some statistics, this lesion seems to be a rather unusual one. Besides, they were seen earlier than most reported cases, which is an important factor as we must make earlier diagnoses in this group if we are to have even an early mortality of less than one 100 per cent. The cancer mortality from breast carcinomas is already very high but these cases are practically always rapidly fatal. The first patient presented a lesion which was only moderately advanced for this type but died within a few months. The next patient, a little more advanced, disappeared after I had examined her and the third case is still living but the condition is only a few months old. (Since writing this report, the third case has died of local, cerebral and massive lung metastases, six months after operation.)

CASE I. Mrs. T; English by birth; thirty-nine years old. Married for twelve years; had three children, eleven, five and three. She was stout and well-nourished which condition persisted until a very short time before her death. She was sent to me for examination of the left breast. Stated that a few weeks before she noticed that the left breast was thickened and she thought it was slightly enlarged. She felt no pain but rather a sort of burning sensation. She consulted a doctor a few days previous to my examination for the first time. Stated she nursed her first child but was unable to nurse the others.

Examination showed a rather stout woman, 5 ft. 5 in. tall; weight 180 pounds. The general physical examination showed nothing abnormal. Breasts were pendulous and large. There was a thickening of the left breast; the skin was a little edematous and pinkish, not a marked redness. There was a diffuse thickening of the whole breast tissue and a slight tenderness. The nipple was normal in appearance, but on squeezing, I found a slight serous discharge. The temperature was 99.6°F.; pulse 84. There

was no history of chills nor acute onset. From the appearance of the breast, I believed this was a mild inflammatory condition aggravated by the pendulous condition. I ordered elevation, rest in bed and hot moist applications.

One week later she reported and was much improved. The tenderness was nearly gone; the edema not so marked and the pink color almost absent. I ordered a continuation of the same treatment. At the end of another week she returned feeling less comfortable, but as she had only partially carried out my orders, I told her to continue as she had been doing: that is, elevation, heat and bed rest.

I saw her again in a few days in which time the pain and tenderness had increased and the redness and edema were more marked. I sent her to the hospital with the idea of opening a deep abscess. On cutting into the mass I found what appeared to be a definite malignancy. Therefore had sections made and did a radical removal. Enlargement of a few axillary glands was beginning. The immediate convalescence was normal; but three months later signs of lung involvement appeared and in a few weeks she was dead, of extensive metastases both local and general.

CASE II. This patient presented herself for examination a few weeks after the first one. She was forty-one years old; unmarried, rather stout and had large pendulous breasts. The history was of a thickening noticed some few weeks before and of discomfort, pain and burning for the past few weeks. The right breast was involved.

Examination showed a large, pendulous, right breast with considerable thickening. The skin was pink and slightly edematous. No retraction of the nipple and no palpable glandular enlargement. I advised deep x-ray therapy, but did not see this patient again. She had very definitely the same type of growth we found in the first instance.

CASE III. This patient came in for examination about four months ago. A large woman; fifty years old, married, but had borne

* Read before the Pacific Coast Surgical Association, Santa Barbara, Calif., February 22-23, 1929.

no children. She first noticed thickening of the left breast two months previous. There was slight pain, burning and tenderness for only a few days. The breast appeared slightly enlarged and there was an indefinite tumor mass. The skin was slightly edematous and slightly pinkish but was not reddened. This was localized to an area 2 in. in diameter around the nipple. There was no palpable glandular enlargement. The breast was quite sensitive to the touch. This, as in the other cases, looked like a mild inflammatory process, but in the absence of history suggesting an infection, I advised a radical removal. I did this believing that this was an inflammatory carcinoma but I thought it possible that being a relatively early case, operation might offer something. I knew also that nothing else offered any relief.

She did not come in for operation till two weeks later, at which time the edema was very, very much less and had almost disappeared, the mass, however, remaining the same. I did a radical removal and found the same pathological picture that I found in the first case, a rapidly-growing soft carcinoma. This case is only four months old so I cannot as yet say what the outcome will be. (I have previously given the outcome of this case.) I may add that before the operation I had her chest x-rayed and this was negative. Both cases had x-rays taken after operation.

These three cases were early examples of the typical inflammatory carcinoma in which the skin becomes red or purple, edematous and erysipeloid. This condition is present from the very beginning and is not to be confused with the same picture which may occur in the course of a more advanced carcinoma.

It is of particular interest in the first case that the redness and the edema varied over a period of three weeks and the same thing was true in the last case, the edema present on first examination being much more marked than two weeks later at the time of the operation.

Bell in 1841 in discussing breast carcinoma said: "When a purple color is on the skin over the tumor accompanied by pain, it is a very, very unpropitious beginning."

Several other observers, among them Klotz and Volkmann, have described the

same condition occurring in the lactating breast. Billroth in 1871 and Rodman in 1889 each described this lesion. Schumann reported 11 cases including one of his own and more recently Lee and Tannenbaum reported 28 cases. According to their statistics this condition occurs in 1.3 per cent of all cases of breast carcinoma. Since then Lee has collected 100 cases.

The condition is frequently very acute and does not respond in any way to the usual treatment. The initial symptoms are heaviness and burning of the breast and increase in size. The increase is ordinarily diffuse but there may be a partially defined tumor not, however, of the usual stony hardness. It has occurred most frequently in pendulous breasts and one half of the cases are nullipara.

Early in the disease there are skin changes simulating low grade inflammation. Retraction of the nipple occurs late and the nipple may become edematous. Glandular involvement appears early. Later the skin becomes deep red or reddish purple and is hard and infiltrated. This description I have taken from Lee and Tannenbaum's paper as my cases were seen early and did not show this change so markedly. The infiltration is like erysipelas and may be extensive. There may be a temperature of 100° F. blood picture shows nothing. Later in the course minute areas of ulceration occur but there is no breaking down en masse. Pulmonary metastases are rapidly progressive when they occur. The patient's general nutrition remains good until late in the disease. The inflammatory symptoms appear early and are present apparently from the very beginning. As stated before skin involvement may appear later in other breast cancers but this is not the type of case under discussion.

In a considerable series of cases the age varied from twenty-six to fifty-one, average being forty-four. Lactation has no apparent effect, being present in approximately 50 per cent of the cases. The differentiation must be made practically only from

abscess. Absence of an etiological factor, an ill-defined tumor, slight if any temperature elevation and no leucocytosis, should clear the diagnosis.

Sections of both these breasts showed a medullary carcinoma with a small amount of connective tissue stroma. I am sorry to say I did not section the skin as it is involved early and certainly would have shown invasion by carcinomatous cells, particularly in the first case. Lee has obtained cultures of streptococcus viridans from macerated tissue in one case.

TREATMENT

Radiation possibly offers more than anything else in the advanced cases as a palliative measure. As a matter of fact, the advanced cases do poorly under any

sort of treatment. Surgical removal has seemed to hasten the course. I would not again operate on a case as advanced as the first one. The third one seemed much earlier and I thought it possible that removal would offer more than x-ray, but the outcome proved that my judgment was wrong.

If we are to accomplish anything we will have to see these patients earlier than most of those reported. If so, it is possible that by an early diagnosis and early treatment, some may be saved.

I have avoided any reference to the use of the cautery as it seems to me that if the disease has infiltrated the tissues diffusely, it will certainly not make any difference and if it has not, removal with the knife will be sufficient.

VAGINAL CESAREAN SECTION

WITH CASE REPORT*

ANTHONY WOLLNER, M.D.

THE indications for vaginal cesarean section being quite limited, suitable cases are rarely seen. Perfection of the technic and variations in the methods of abdominal section have placed the vaginal operation in the background. Since Duehrssen introduced the vaginal section into obstetrical surgery in 1896, the indications for the operation have undergone numerous changes, the low cervical and extraperitoneal modifications of abdominal cesarean section having almost entirely superseded the vaginal operation. Although the popularity of abdominal cesarean is justified, there are, nevertheless, certain cases encountered in obstetrical practice in which the vaginal section is preferable. This is well illustrated by the following case:

K. B. thirty-five years of age, white, female, came under my observation on December 13, 1928. The patient being in a semi-conscious

condition, the following history was secured from her family physician:

Family History. Father died at thirty-four, following a cranial operation which revealed cerebral syphilis. Family history otherwise negative.

Past History. No previous illnesses with the exception of anemia and nervousness at twenty-one years of age, diagnosed as chlorosis.

Menstrual History. Began at fourteen, six to seven-week interval, duration four to five days. Prior to each menstruation, patient had hot flushes in the head and neck; backache and cramps for the first two days of the period.

Marital. Married four years. Pregnancy 1924, miscarriage of six to seven-week fetus, following an accident.

Present Illness. The patient was first seen by her family physician in February, 1928.

Physical Examination. Heart normal, lungs clear, all reflexes slightly increased, slight anemia.

Urine Analysis. Faint trace of albumen.

Uterus. Anteverted, slight erosion of cervix with profuse discharge. The erosion was

* Read before the Section on Obstetrics and Gynecology, N. Y. Academy of Medicine, November 26, 1929.

treated with silver nitrate applications, with marked benefit. Adnexa normal.

May 26, 1928, patient complained of nausea and vomiting in the morning during the preceding two days. Last menstrual period began April 28.

Examination. Bluish discoloration of the cervix, uterus slightly enlarged and soft. Left ovary enlarged to size of a walnut. This was thought to be the corpus luteum gravidarum. On subsequent examination the left ovary was found the same size, and the uterus enlarged progressively as in normal pregnancy.

There was no change in the patient's condition until November 7: Blood Pressure 140/80; fundus one finger above umbilicus; fetal heart sounds loud. Urine analysis as on previous examination.

November 14, patient complained of pain in the lower abdomen and right upper quadrant. Rest in bed and a restricted diet were prescribed. The pains disappeared after six days.

November 23, pains of same character recurred, with impairment of vision. Patient complained of seeing small black spots. B. P. 180/100. Fetal heart sounds of good quality. A more strict diet and a belladonna preparation were prescribed.

November 30, patient complained of uterine cramps and slight bleeding from the vagina. Size of uterus that of a six to seventh-month pregnancy. Urine analysis albumen 0.27 per cent; moderate number of hyaline and few granular casts.

December 1, patient restless, complained of insomnia, severe headaches, and apprehensive. Blood chemistry; non-protein nitrogen 67.57 per cent. Increased impairment of vision. Cessation of bleeding on the following day.

December 6, ascites. B. P. 210/110; pulse 100, increased impairment of vision. Patient was removed to the hospital. Eye ground examination; small effusions and papillary edema, diagnosed as albuminuric retinitis. Consultants advised waiting for spontaneous delivery and the patient was discharged.

December 8, no fetal heart sounds heard, patient no longer felt life; restlessness and headaches more marked; patient could not distinguish the number of fingers at a distance of ten feet. B. P. 190/100, pulse 105.

December 13, attack of dyspnea, chill, short period of unconsciousness. I was then called in consultation.

The clinical picture was that of a grave

toxemia of pregnancy and immediate interruption of the pregnancy was indicated. Because of the intensity of the toxemia, the method of interruption affording the quickest and most painless termination was selected. Cervical dilatation and the introduction of a bag were considered inadvisable for the following reasons: (1) because the rigid soft parts of an elderly primipara might not dilate sufficiently, and (2), because this method would not exclude labor pains. The choice for a rapid delivery lay between the abdominal and vaginal section. Because of the fact that the fetus had been dead for the last ten days, abdominal section was not justifiable, particularly since the much less dangerous procedure of vaginal section was available.

DESCRIPTION OF OPERATION

Usual preoperative preparation, disinfection of the vulva and vagina with green soap and douching; catheterization. Vaginal retractors are introduced and the cervix visualized; two vulsella applied at either side of the median line and the cervix drawn downward. A transverse incision is made on the anterior surface of the cervix, going through the vaginal mucous membrane. The bladder is pushed upward from the anterior cervical wall, using one finger covered with gauze for this purpose (the bladder is separated very easily from the cervix in pregnant women). The bladder is pushed upward until the uterovesical fold of peritoneum can be visualized at the upper angle of the wound. The bladder is retracted by the insertion of a narrow speculum, and in this manner the anterior wall of the cervix is exposed. Traction is made with the cervical vulsella and the anterior wall of the cervix is split with scissors in the median line up to the internal os. This brings the bag of waters into the opening (up to this point in the operative procedure there is practically no hemorrhage). When the bag of water is opened, the liquor amnii is evacuated. The size of the opening into the uterine cavity is now tested by means of the introduction of the closed fist, and determination is thereby made of the adequacy of this opening for the extraction of the fetus. The fetus being non-viable, delivery may be accomplished by means of craniotomy. After perforating the cranium a large portion of its contents is removed. At this stage of fetal development the cranial bones are soft and thin. The use of a cranioclast is contra-

indicated, and delivery is accomplished by means of version and podalic extraction. In this case version and extraction were accomplished without difficulty, and a macerated seven-month fetus delivered. The placenta and membranes were expelled by gentle expression after a ten-minute period. Previous to the versional extraction all instruments are removed from the vagina in order to gain more space and prevent injury to both the maternal tissues and the hand of the operator. Upon completion of the delivery the instruments are reapplied and the operative field inspected. In this case it was found that the incision on the anterior surface of the cervix had not been extended by tearing and the hemorrhage did not exceed that of a normal delivery. One cubic centimeter of obstetrical pituitrin is injected into the wall of the cervix before suturing. Traction is made on the vulsella in order to bring the uppermost angle of the wound into view; interrupted chronic catgut sutures are used, which extend through the muscularis but which do not include the mucosa. The uterine cavity is packed with gauze, and a strip of gauze is left in the subperitoneal wound for a twenty-four hour period. The vaginal edges are united by means of interrupted catgut sutures. The duration of the operation in this instance was thirty-five minutes.

POSTOPERATIVE PERIOD

The rapid recovery following operation in this case was remarkable. Ten hours postoperative the patient did not give one the impression of an operative case. There were none of the usual signs of the after effects of a laparotomy; with the exception of slight uterine contraction, the patient complained of no discomfort. The temperature rose to 100°F. on the first day; after this it remained between 98.8° and 99.4°F. The pulse rate remained unchanged and was about 100°F. as before operation. On the sixth day there was a gradual decrease of the pulse rate and this became normal on the tenth day. A considerable improvement in vision was noted as early as the first day. On the second day the patient could distinguish the fingers of a hand, and there was continuous improvement until the tenth day, when the patient was able to read. The urine which had shown a four plus albumen reaction prior to the operation was two plus on the sixth day and continued so

until the patient was discharged from the hospital. Blood pressure on the fourth day was 140/88, on the tenth day 130/86. The patient voided spontaneously from the first day. Examination on discharge revealed a normally involuted uterus and normal adnexa. Vaginal examination showed primary union of the incision and a normally shaped cervix.

In this operation I deviated in two respects from the usual technic of vaginal section. As a rule the operation is commenced with a deep episiotomy. This shortens the length of the vaginal canal, makes the cervix more accessible, and prevents the irregular tears of the vagina and perineum during the extraction of the fetus. I do not feel that the episiotomy is advisable, as there is considerable hemorrhage from the incision. This is occasionally difficult to check and consumes valuable time. In many instances there is a greater loss of blood from this procedure than from the vaginal section itself. If the section is performed in a case of prematurity or in the case of a mature but dead fetus, where the delivery can be accomplished by means of craniotomy, we do not have to anticipate injury to the vagina or perineum. In those cases in which a mature living fetus is delivered there may be a need for episiotomy, but in these cases it may be done at the time when it becomes imperative.

Another deviation from the routine procedure was the use of one anterior incision only, on the cervical wall. Duehrssen insists that two incisions be made; one anteriorly and one posteriorly. Most obstetricians familiar with the method are in accord with Duehrssen. We, however, share Bumm's opinion and find that the anterior incision, if extended, gives sufficient space for even a full-term child. The omission of the episiotomy and posterior incision of the cervix shortens and simplifies the method considerably and therefore makes the operation of greater value in toxic cases.

Vaginal cesarean section involves two important hazards which one must care-

fully avoid. One of these is injury to the bladder or ureters. This can be obviated by reaching the proper layer when making the first transverse incision; it must extend sufficiently through the vaginal mucosa. If one reaches the proper layer there is no difficulty in pushing the bladder upward by means of one gauze wrapped finger. Should there be any difficulty in locating the bladder, its lowest point may be located by means of the introduction of a metal catheter.

When the bladder has been pushed upward to the required extent, one must be sure it is well retracted so that there is no danger of injury when the cervical incision is made. Anyone experienced in pelvic surgery should have no difficulty in avoiding injury to the bladder. Before placing the cervical sutures the bladder should be catheterized to make certain that it is undamaged.

An additional point that must be borne in mind is that the cervical incision may extend by tearing during the delivery of the fetus. Should this tear directly upwards into the corpus of the uterus, it may open the peritoneal cavity; but this is not a serious complication if it is repaired promptly. On the other hand, should this tear extend in a lateral direction toward the parametrium, there is danger of rupturing the uterine artery or vein, with profuse hemorrhage. Such an accident may necessitate the ultimate removal of the uterus. However, if the original incision of the cervix is absolutely in the median line and of sufficient extent, there is no likelihood of a lateral tear. One must remember before making the cervical incision that the cervix may be rotated to one side, and careful examination must be made therefore before the incision. There is no hemorrhage from the cervical incision if done correctly and if traction is made on the vulsella. If the cervical incision is made up to the peritoneal fold there is ample space for the passage of a mature fetus, as this incision is as extensive as that of a low cervical cesarean section.

Difficulty may be experienced in attempting to deliver a mature fetus through the unprepared vagina. If forceps is applied, or if version is done, and the extraction of the aftercoming head is done too rapidly, laceration is more likely.

In the delivery of a mature living fetus one may be faced with a situation where there is a conflict between the interests of the mother and that of the child. If one is too cautious in the delivery of the fetus it prolongs the operation and imperils the life of the child. On the other hand, if a rapid delivery is accomplished, the upper portion of the vagina can hardly escape grave injury. This presents a paradoxical situation for the obstetrician, and it is for this reason that we do not advise vaginal cesarean section in cases where one is dealing with a mature living child. In such a case, the apparent advantage of vaginal section is outweighed by the resistance offered by the unprepared vagina during delivery; in the case of a mature living child preference should always be given to the abdominal operation.

In those cases where the fetus is premature or is mature but dead, the above mentioned dangers are of less importance, and in this group the vaginal cesarean section has decided advantages. The convalescence following a vaginal section is more rapid and the usual unpleasant symptoms following laparotomy are avoided. The patient regains her strength and resistance in an amazingly short post-operative period, which is of special significance in cases of toxemia. The vaginal cesarean section obviates exposure of the peritoneum and the duration of the operation is shorter. There is no record in the literature of any complication in subsequent pregnancy or labor because of the cervical scar. Another advantage of this operation is the avoidance of peritoneal infection as the entire procedure is extraperitoneal.

CONCLUSION

In cases where one is dealing with unpre-

pared softs parts and where a rapid painless delivery is essential, one has the choice of either abdominal or vaginal section. The decision should depend entirely on the condition and age of the fetus. If the fetus is mature and alive, abdominal cesarean section is the method of choice and gives more satisfactory

results. If, on the other hand, the fetus is premature, or is mature, but dead, the vaginal cesarean section should be performed. The indications for vaginal cesarean section are very limited; but in properly selected cases the advantages which it offers are unsurpassed by any other method.

COSMETIC RESULT IN A CASE OF MARKED SCOLIOSIS

WITH ROTATION OF THE RIBS TREATED BY CONVEX FRAME, SPINE FUSION AND RIB RESECTION*

JOSEPH BUCHMAN, M.D., F.A.C.S.

BROOKLYN, NEW YORK

A GIRL fourteen years old was admitted to the Hospital for Joint Diseases on August 15, 1928, with the complaint of deformity of the back of two years' duration. Examination showed a very marked right

dorso-lumbar scoliosis with marked rotation of the ribs to the right, and a collapse of the trunk, as shown in Figure 3. After being kept on a convex frame for several months, the patient was operated upon by Dr. Samuel

FIG. 1. Anteroposterior roentgenogram of spine before operation.

FIG. 2. Anteroposterior roentgenogram of spine eight months after spine fusion. Note improvement in curvature. The beef bone graft is beginning to be absorbed. There is considerable bony callus formation.

* Presented before Section of Orthopedic Surgery, New York Academy of Medicine, October 19, 1929.

FIG. 5.

FIG. 3. Appearance of back before operation. Note sagging and shifting of trunk to right and marked rotation and prominence of ribs on right side

FIG. 4. Appearance of back after spine fusion and rib resection.

FIG. 5. Appearance of back when apparent shortening of right lower limb is compensated by an inch lift of right shoe.

FIG. 6. Tracing of back at level of the tenth dorsal vertebra before and after rib resection to show improvement in deformity.

Kleinberg, who performed a spine fusion from the fifth dorsal to the second lumbar vertebra, and inserted a beef bone graft on the concave side of the curve. Ten days later the patient was replaced on a convex frame and on February 1, 1929, the child was discharged wearing a plaster of Paris jacket.

She was readmitted to the service of Dr. Kleinberg, at the Hospital for Joint Diseases on August 20, 1929, for the correction of the deformity due to the rotation of the ribs.

Examination at that time showed that the back was markedly improved, that the operated area was stiff, that the patient's posture was considerably improved, and that she was

several inches taller than on the previous admission. It was also noted that there was an apparent shortening of the right lower limb of 1 inch. On August 23, 1929, a rib resection, as advocated by Dr. Armitage Whitman, was performed by me. I removed about two and a half to three and a half inches of the sixth to the eleventh ribs inclusive. Eleven days later the patient was placed on a convex frame and four weeks thereafter she was discharged, markedly improved in appearance and in general condition.

This case was presented to demonstrate the cosmetic result obtainable by means of the convex frame treatment, spine fusion and rib resection.

MYXOGLOBULOSIS OF THE APPENDIX*

W. C. HUEPER, M.D.

CHICAGO, ILL.

RETENTION cysts of the appendix with mucous content were first described by Fraenkel in 1901 and appear in the literature under various names as hydrops of appendix, colloid or pseudomucinous cyst, myxocoele, mucocoele, mucinous cyst, pseudomyxoma, etc. They are rather rare, if a correct conclusion can be drawn from the number of cases reported. Weaver¹ collected 168 cases in 1928 from the literature. An uncommon variety of this condition is the myxoglobulosis (Hansemann²) or the fish egg appendix (Morrison³). Weaver found only 8 cases recorded of this type which number Hudacsek⁴ could increase to twelve in 1929. The condition is characterized by the presence of globoid bodies of mucinous character in the cystic content resembling in their gross appearance fish eggs. These balls vary considerably in size and may reach one centimeter in diameter. They contain occasionally calcifications. They represent inspissated balls of mucoïd material around minute masses of necrotic material and are composed

of mucin and pseudomucin sometimes arranged in concentric layers. The lumen of the appendix is more or less distended and lined by a straight, sometimes stratified layer of cylindrical mucus-producing cells of goblet cell type. With the increasing pressure of the mucous content degenerative changes of the epithelial cells may occur, resulting in a self-limitation of the process. The submucosa is fibrous and contains no or very little lymphoid tissue. A mucinous imbibition of the submucosa is sometimes observed. The muscularis is usually thinned, but also hypertrophy may be seen (Hudacsek⁴). Stenosis of the lumen at the cecal os with continuation of the mucus production by the mucosa and with absence of an infection is regarded as the causative mechanism of this condition. The stenosis may be due to a constrictive scar formation from a preceding appendicitis (Aschoff⁵), or due to angulation, torsion, compression by adhesions, invagination into the cecum, foreign bodies or parasites in the lumen of the appendix. The clinical symptoms

* Submitted for publication December 30, 1929.

produced are usually those of a chronic appendicitis. As secondary complications, we find listed, ileus, volvulus and rupture

of admission was negative with the exception of a slight tenderness and rigidity in the lower right quadrant showing no increased tender-

FIG. 1. Myxomatous area in submucosa.

of the appendix with subsequent pseudomyxoma peritonei (Morrison,³ Wegener⁶), which, according to Hudacsek,⁴ shall differ in prognostic respect from that following a ruptured ovarian cyst. While the latter is, as a rule, fatal in spite of surgical interference, the former offers a good prognosis. In Hamdi's⁷ case only were metastases found in the liver and breast, so that Hudacsek claims they were of benign nature.

CASE REPORT

Mr. M. K., thirty-five years old, had for the last three years attacks of pain in the lower abdomen which were acute in onset, cramp-like in character and lasting from a few hours to a couple of days. They appeared in intervals of weeks and months and had not increased in severity. The last attack was similar in character to those previously observed, but the pain became most prominent over McBurney's point. There was no nausea or vomiting present. The physical examination at the time

FIG. 2. Papilloma with atypical epithelium and portion of mucous globule.

FIG. 3. Hyperchromatic, atypical epithelium lining portions of appendix.

ness upon palpation of this region. But an elongated mass was felt here. Blood count: 6700 leucocytes, 47 per cent polymorpho-

nuclear neutrophiles, 43 per cent lymphocytes, 6 monocytes and 4 eosinophiles.

Operation: the appendix was 15 cm. long and 3 cm. wide. The subserous vessels were hyperemic. The base of the appendix appeared to be invaginated into the cecum for a distance of 1 cm., so that it had to be dissected out of the intestinal wall by the knife. The amputated appendix appeared to be filled with a smooth substance of paste-like consistency. The different layers of the wall were easily discernible. The lumen of the appendix measured 2.5 cm. in diameter. After the appendix was opened by a longitudinal section, a mass was removed consisting of smaller and larger yellowish white, opalescent globules surrounded by a clear gelatinous material.

The *microscopical examination* showed a mucosa consisting of a single, straight layer of high columnar, mucus-producing cells. The lining was frequently defective. The cylindrical epithelium showed evidence of regressive changes at the periphery of the defects. The cells became gradually lower and smaller till they disappeared completely as a delicate, dark line. Glandular formations were only occasionally seen. The submucosa was fibrous in character and more or less densely infiltrated with eosinophilic cells, leucocytes and lymphocytes. In the cecal portion of the appendix areas of mucinous imbibition of the submucosa were encountered (Fig. 1). The epithelial lining covering these myxomatous zones consisted of narrow, dark-stained, indistinctly outlined cells. The muscularis was thickened and showed an eosinophilic and lymphocytic infiltration of moderate degree. The mucoid globules consisted of mucin and pseudomucin and were sometimes surrounded by a leuco-

cytic coat. In a section from near the cecal end a small papilloma was present. It showed a very vascular loose stroma with finger-like projections covered by a rather irregularly shaped, somewhat vesicular epithelium with round, hyperchromatic nuclei. The epithelium of the adjacent parts of the appendix was composed of similar cells (Figs. 2 and 3).

CONCLUSIONS

It is thought that the small papilloma was the cause of peristaltic contractions of the appendix resulting in its invagination into the cecum. The compression of the cecal os of the appendix thus produced is the cause of the retention. The continuation of peristaltic movements may have produced the globular arrangement of the mucus. Considering the rather atypical character of the epithelial lining of the papilloma, a rupture of the appendix might not have proved as harmless as generally observed.

I am indebted to Dr. P. Kreuscher for the history of the case.

ANATOMIC RESTITUTION OF A FRACTURED CLAVICLE¹

EDGAR M. BICK, M.D.

NEW YORK

THE fractured clavicle as usually met in general practice causes no great concern to the surgeon. Any one of the

usual adhesive strapping had been applied immediately after the accident, but a protrusion due to the overriding outer fragment,

FIG. 1.

FIG. 2.

many accepted methods of partial immobilization offers the probability of an excellent functional result. However, the frequent residual swelling and decrease in the width of the shoulder, while unimportant to the steel worker, may be objectionable to the lady whose evening dress forms an essential part of her wardrobe. This report concerns such a case. At the suggestion of Dr. Armitage Whitman, in whose care the patient was placed, the following method of reduction was successfully applied. We believe it to be original and useful.

Mrs. E. G., aged twenty-nine, fell from her horse two and a half days before admission to the hospital, fracturing her clavicle at the juncture of the middle and outer thirds. The

and the coincident asymmetry of the shoulders caused considerable anxiety. She applied for further treatment to reduce the deformity.

Her past history and general physical examination are irrelevant. There was no pain, very little tenderness, and no circulatory or nerve disturbances. In short the case was that of a typical "broken collar bone."

A roentgenogram confirmed the diagnosis, and is herewith presented (Fig. 1). The left clavicle between the middle and outer thirds is fractured transversely; the outer fragment overrides about 2 inches.

The patient was taken to the operating room and placed upon a Hawley table. Her head and neck rested upon the shoulder piece; her waist and hips upon the main body piece. The shoulder piece was pulled out as far as possible, leaving the back of the patient exposed except for the narrow metal strip connecting the two parts. In this position the shoulders and back were free for manipulation. A double layer of felt $2 \times 3 \times 4$ in. was placed between the scapulae, resting on the connecting strip. This served to elevate the interscapular region.

¹ From the First Orthopaedic Service, Dr. Royal Whitman, Hospital for the Ruptured and Crippled, New York City. Submitted for publication October 11, 1929.

The left arm was allowed to drop posteriorly and then brought to 100° abduction. This position was maintained by an assistant. It must be emphasized that the posterior drop of the arm and shoulder was entirely gravitational. The opposite shoulder, unrestrained, serve as a balance.

In this position it was apparent to the operators that the protrusion over the site of fracture had disappeared. Sheet wadding was wrapped about the left arm and shoulder, and around the trunk from the axilla to the iliac crests. Over this a plaster-of-Paris spica was applied. The head piece was pulled cephalad, thereby removing the connecting rod from the spica, and the patient was placed on a stretcher. Shortly afterward the plaster was trimmed, exposing the clavicular area, and a portion was removed over the anterior surface of the forearm and antecubital space. This permitted motion at the elbow, and the patient could use her left hand in eating, card-playing, etc. (Fig. 2).

After forty-eight hours the patient was permitted to sit up in a chair, and even to walk. A second roentgenogram taken a few hours after reduction shows complete restitution of the fragments to their normal positions (Fig. 3).

Thirteen days later the spica was removed. The symmetry of the shoulder was perfect.

A slight swelling over the site of fracture, while palpable, was barely visible. The patient was then given a supporting sling, mainly

FIG. 3.

as a reminder to care for the shoulder during an impending long train voyage.

This method of reduction is one to be used in those cases of fractured clavicle in which anatomic restitution is necessary to prevent deformity. True, it appears cumbersome, but ten to fifteen days so spent may save many moments of embarrassment later.

TWO INTERESTING HAND CASES*

LEO MAYER, M.D.

NEW YORK

MY purpose in the case reports is to illustrate methods of conserving tendon function and to show the technic of tendon transplantation which is applicable to this type of injury.

CASE I. A young boy cut his hand on a milk bottle a year ago. As is well known, milk bottle injuries are invariably infected; I have never heard of any that did not become infected. The physician who saw him did not try to attach the tendon at the time of the accident; he put in a drain and let the wound granulate, and at the end of three weeks referred the boy to me. The wound was well

healed. Cutting down on the tendon, I found the flexor profundus and flexor sublimis of the third finger had been cut through, leaving a space of about 2 in. between the two ends. Traction on the proximal stumps did not appreciably lessen the gap.

In a case of this kind, the simplest and most effective procedure is to sacrifice the sublimis and concentrate on the profundus. The operation is done by splicing a graft taken from the sublimis tendon between the stumps of the profundus tendon. The operation takes about forty minutes.

The postoperative care of these cases is

* Read before the Section of Orthopedic Surgery, N. Y. Academy of Medicine, January 18, 1929.

tedious. Three or four months are required before proper function is restored.

The action of the transplanted tendon in this case is not 100 per cent perfect. I have not succeeded in getting perfect results; there is always a little slack in the tendon that I have not as yet been able to correct. This boy uses his fingers together very well, but on trying to use the third finger alone he cannot get it quite to the palm. The operation requires a rather fussy technic; we must operate quickly, for we cannot leave the Esmarch bandage on more than an hour.

The next case is an altogether different type:

CASE II. The patient scraped his hand on a nail, and developed a small infected spot on the dorsum of the hand. The infection looked very mild and I opened the abscess under novocaine. Some hours later the patient telephoned and reported that he was suffering severe pain, and on seeing him I found the wound surrounded by a black area about the size of a silver dollar. It made me suspect anthrax, and I rushed him to Dr. Stetten, who also suspected anthrax. I made a broad excision of the blackened tissues and packed the wound with hexylresorcinol. Despite the excision, his temperature rose to 102°F. the wound edges sloughed, and the infection continued to spread. A few days later I attempted a second excision and found that the infection had involved the entire dorsum of the hand; the skin was eaten away, the fascia was gone, etc., and the infection had extended up about two-thirds the distance to the elbow. The cultures

showed no anthrax bacillus only staphylococcus, with nothing peculiar about it except that it grew in anaerobic as well as in aerobic cultures.

At that time the patient was seen by Dr. Stetten and Dr. Herold Neuhoof.

I was very much disturbed, for the patient was a well-known violinist, and I thought he would never play the violin again. Dr. Neuhoof thought it looked like an anaerobic infection and advised the use of hydrogen peroxide. I got an arm bath and filled it with warm peroxide, and immersed the arm in it. In an hour the condition was slightly improved; in three hours the wound looked definitely better, and it was evident that the infection had been checked. Within two days, the wound looked normal, and in a week's time the entire hand was covered with healthy granulations.

Then came the question of how to cover that huge granulation area. Of course, it is necessary when dealing with skin over a superficial joint to use either a Wolff graft or a pedunculated graft. I removed a flap from the abdominal wall 11 in. long by 4½ in. wide. The graft healed very nicely. The patient has complete control of his fingers and is able to play the violin as well as ever.

The graft seems smaller than at the time of the original implantation; the cosmetic effect is not entirely satisfactory, owing to the thickness of the graft, but I hope to be able to improve that later. The most interesting point, however, is that we were able to save the function of the tendons. Another interesting thing is the ingrowth of the nerve fibers from the upper part growing downward, so that the patient has sensation over one-fourth of the graft.

MESOTHELIAL TYPE OF MALIGNANT HYPERNEPHROMA

WITHIN A SOLITARY CYST OF THE KIDNEY*

J. SYDNEY RITTER, M.D.

NEW YORK

MRS. M. T., aged thirty-seven years, married, was referred to me on July 6, 1927 by Dr. L. A. Shifrin. At this time the patient complained of a palpable mass filling the right side of the abdomen together with severe, piercing pain in this region which radiated dorsally.

The family and past histories were irrelevant.

The present illness dated back to March 1927, on which date the patient had a similar attack of pain and fullness which lasted a few hours.

On her first examination the physician made the diagnosis of a possible ovarian cyst; however, when examined by a gynecologist a week later a definite denial of an ovarian cyst or any tumor was made. She had had three other attacks following this one with similar experiences and not until the patient came under the care of Dr. Shifrin was renal disease suspected. He suggested a complete urological examination. From the history of the case we made a tentative diagnosis of intermittent hydronephrosis, the causative factor not being determined, but advised hospitalization for study.

July 6, 1927, she was admitted to the New York Post-Graduate Hospital, at which time the complete examination was made:

Physical Examination: Fairly well-nourished adult, female, weighed about 128 lb., in good general physical condition. Heart and lungs were normal. Abdominal palpation revealed a firm, tender, palpable mass in the upper right quadrant which extended down into the pelvis on the right side.

By vaginal examination this mass was found not to be attached to the uterus, as shown in Figure 1.

Cystoscopic Examination: A No. 24 McCarthy cystourethroscope was introduced. The bladder was found to be trabaculated. The vesical sphincter was normally located and normal in appearance.

Indigo carmine injected intravenously appeared on the left side in three minutes with good concentration in five; from the right side the dye appeared in eight minutes, with a 3 plus concentration in eleven.

Ureteral catheters were passed to both renal pelves without difficulty. Urine obtained from both sides was clear and negative but for a faint trace of albumin.

A pyelogram was then made on the right side, using 15 c.c. of a 12.5 per cent solution of sodium iodide. The patient complained of some pain in the region of right kidney. An x-ray exposure was made. The catheter was withdrawn and the ureter distended with sodium iodide and another exposure was made. Several x-rays were taken prior to the pyelogram.

X-ray Report (Fig. 2): July 6, 1927. Examination of the genitourinary tract shows the left kidney to be of comparatively normal shape, size, position and illumination; the lower pole was opposite the upper border of the third lumbar vertebra.

Examination of the right kidney after the injection of the contrast substance showed the kidney much enlarged. The enlargement was mostly towards the lower part. The lower pole was below the iliac crest. The kidney pelvis appeared to be normal. The calyces were somewhat irregular (Fig. 2). Diagnosis: solitary cyst or tumor of kidney.

Operation. On August 12, 1927 this patient was operated on. Through a right hockey stick incision the kidney was exposed; the upper pole was easily delivered, due to the fact that the entire kidney was rotated and pulled down out of its former location. From about the middle of the convex surface a distinct cyst-like tumor was found to be firmly incorporated with the kidney and extending well down into the pelvis. Due to some adhesions between the cyst wall and the peritoneum it was necessary to open into the peritoneum to determine the extent of the mass and the possibilities of its attachment to any intra-abdominal organ. I was particularly anxious as to its being in any way associated with the ovary and as to its relationship to the ascending colon.

With one hand in the abdomen I was able to free the peritoneum from the tumor; however this was not accomplished until I had separated the growth from the kidney. On

* Read before the Section of Genito-Urinary Surgery, N. Y. Academy of Medicine, Dec. 18, 1929

cutting the tumor I noted a large clot of old coagulated blood together with many papillomatous masses lining the cavity.

FIG. 1.

Due to the fact that some of the tumor was attached to the kidney a nephrectomy was done. On the operating table a diagnosis of cyst-adenoma simulating that of the ovary was made. The wound was closed in the usual

FIG. 2.

manner and patient returned to bed in good condition.

Pathological Report (Fig. 3): One specimen is a small kidney measuring 95×43 mm. It has been removed with a small portion of ureter. At the convexity there is an excavation, ellipsoid in shape, which occupies a length of 55 mm. and a width of 33 mm. This excavation is more or less smooth walled, with a small amount of kidney tissue projecting in an irregu-

lar fashion. At one edge there is a small papillary projecting tumor nodule which apparently has been torn off from a larger cystic tumor

FIG. 3.

node. This small nodule measures $15 \times 15 \times 14$ mm. It appears to be in connection with a tumor invading the kidney cortex proper which reaches a diameter of 14 mm. This invasive portion of the tumor can be seen to bulge out on the surface of the kidney opposite the nodu-

FIG. 4.

lar tumor in an irregular fashion for a distance of 19 mm. It is hemorrhagically discolored. The remainder of the kidney substance is negative. The cortical and medullary markings are well preserved. The pelvis and mucosa of the calyces is pale.

The second specimen is apparently a portion of a cyst wall which has been torn in several places. In its interior there are numerous larger papillary projecting nodules and several areas of dark brown, partly hemorrhagic clotted blood. This portion of the tumor, which apparently was in connection with the tumor on the kidney, measures $135 \times 55 \times 23$ mm. The tumor nodules on the interior of the membrane are very firm.

Microscopic Examination (Fig. 4): The papillary material and most of the wall of the cyst are composed of irregularly interlacing bundles of rather large acidophile spindle-shaped cells with irregularly oval vesicular nuclei, only moderately rich in chromatin and usually showing a nucleolus. These cells are frequently fragmented and are more compact and better preserved immediately around the blood vessels. Striations cannot be found in them and they appear not to be muscle cells. Van Gieson stain reveals no collagenous fibrils between them. In general the granular character of their cytoplasm indicates the presence of lipoid, as the yellow color in the gross specimen would also suggest. In some portions there are large globules of fat in the substance; mitotic figures are not recognized.

This is an unusual tumor. It is undoubtedly malignant and local recurrence with eventual extension is to be expected. It would appear to have developed from a remnant of displaced adrenal medulla beneath the renal capsule.

Diagnosis: Mesothelial type of malignant hypernephroma.

Follow-up Report: The further progress of this patient after being discharged from the hospital: She reported to the Memorial Hospital where she has been under the care of Dr. A. L. Dean, Jr., and a personal communication which I received this year is as follows: "I saw your patient, Mrs. M. T., on September 13, 1929. At that time she was enjoying perfect health and a physical examination revealed no sign of disease."

This case appears worthy of report due to the fact that in renal surgery, particularly where a diagnosis of cyst of the kidney has been correctly made, it is not sufficient to merely enucleate the cyst, but before leaving the kidney in situ it is advisable that the cyst be opened and examined for possible neoplastic growth.

It is of interest to attempt to explain the appearance and disappearance of this tumor mass. In the x-ray examination there was no communication between the cyst and the renal pelvis. We cannot therefor consider this to be a case of intermittent hydronephrosis but must accept the interpretation of the appearance and disappearance of the tumor mass as being due to intermittent hemorrhage together with reabsorption of the blood clot.

TORSION OF THE TESTICLE*

CLARENCE B. WHITTEMORE, M.D., F.A.C.S., AND LEONARD ZWEIBEL, M.D.

JOHNSON CITY, N. Y.

THERE are only 137 cases of torsion of the testicle reported in the literature, and it is therefore relatively rare. It is probably more frequent than is generally supposed, owing to the fact that the torsion may be only partial and that it may subside spontaneously with or without infection and under expectant treatment. The torsion consists of the rotation upon its longitudinal axis, causing thereby a sharp twist in the spermatic

cord which may consist of one-half to four turns in either direction. The blood supply is interfered with, hemorrhagic infarct of the testis follows and the gland either goes on to suppuration, or more frequently to atrophy. It is very likely that many of these testes undergo atrophy without being diagnosed.

The etiology is obscure and has not been definitely determined. It is believed to be due to some congenital malformation

* Read before Endicott-Johnson Medical Society December 4, 1929 at Johnson City.

affecting the anchorage of testis and epididymis to its tunical bed, which gives the testis greater mobility than is normal. The undescended testicle is apparently peculiarly subject to torsion. It generally occurs through being induced by muscular effort, particularly of a sudden, severe sort, although it has been reported as having occurred during sleep in several cases. Torsion may occur at any age, but is chiefly seen between the ages of thirteen and twenty-one years of age.

The most frequent torsion is the intra-vaginal type, where an abnormally long mesorchium exists. Others are extra-vaginal, in which the entire testicular mass, including testicle, epididymis and tunica, rotates within the scrotal wall so that the cord is twisted in its extra-vaginal position.

The pathology is commonly agreed upon. The skin and subcutaneous tissues are thickened and edematous. The tunica is infiltrated and contains a thick, almost black, fluid. Usually there is a general thrombosis below the twist which, as previously mentioned, may vary from one-half turn to four turns, and the testicle may undergo hemorrhagic infarction with commonly resulting gangrene, or interlobular hemorrhage or atrophy, which is most common. If infection supervenes from the blood stream, the infarct suppurates and discharges to the outside. If there is simple necrosis with no infection, the exudate is eventually resorbed, the necrotic tissue replaced by scar and complete fibrous atrophy finally results.

The symptomatology is not pathognomonic, although very suggestive. The onset is sudden with severe pain in the testicle and there may be nausea, vomiting and even mild shock, perhaps due to vagus nerve fibers. The temperature may reach 100°F. or higher. Swelling is noticed on the affected side, in either the scrotum or inguinal canal, with redness and edema of the skin which may go on even to an extreme degree. The testicle usually is not palpable in the scrotum due to the

degree of swelling and fluid. Both local and general symptoms are exaggerated when the testicle is in the inguinal canal, and may very closely resemble in symptomatology a strangulated hernia.

CASE REPORT: Infant boy, white, 8 months old, admitted October 8, 1929 to the Charles S. Wilson Memorial Hospital, Johnson City, N. Y. The child had been crying continually since the previous day, as if in pain. Had vomited on the previous day, as well as on the day of admission. Temperature on admission was 100°F. The patient had a fairly severe cough on admission. The mother noticed a swelling in the right inguinal canal since Oct. 7, 1929.

The child was a normal delivery and was normal physically but for umbilical hernia, first noticed at two weeks of age. Had been breast and bottle fed. Family history showed two children in family had whooping cough.

On physical examination, the child did not appear acutely ill, but had convulsive coughing spasms. Pupils reacted equally to light and accommodation. Nose and ears were negative. Tonsils and pharynx were markedly inflamed. Neck was negative. Heart and lungs were negative. Abdomen showed small umbilical hernia and mass in right inguinal canal size of a large walnut over region of external abdominal ring with long axis parallel to Poupart's ligament. The skin over the mass was tense, firm and red. The mass was tender and immobile, apparently adherent to the superficial and deep tissues. The testicles were not palpable in the scrotum. The left testicle was palpable, not enlarged, in the left inguinal canal.

The child had been sent to the hospital with the diagnosis of strangulated hernia.

On admission to hospital, Oct. 8, 1929, after above physical examination, diagnosis was made of: (1) traumatic oedematous undescended testicle on right, (2) upper respiratory infection.

The operation in right inguinal canal demonstrated a tense tunica vaginalis with much thick, dark fluid. There was torsion of the testicle which was gangrenous and appeared with the epididymis like one large undifferentiated hemorrhagic clot. There was marked gangrene and thrombosis extending up the spermatic cord to the external abdominal ring. The right testicle and cord were

removed and herniotomy repair performed (Bassini).

All symptoms but the cough disappeared after operation. The cough disappeared at the end of the third week.

UNUSUAL FOREIGN BODY IN THE CHEEK

RICHARD JOSEPH WHITE, M.D.

FORT WORTH, TEXAS

THE shell of a .22 cartridge in a masseter muscle is, I think, a really unique condition. An eleven-year-old boy was brought to the hospital with a story that three weeks previous in a small town one hundred miles away he had been playing with an old type of single shot breech loading .22 rifle which "broke" in the middle. This was designed for a .22 short cartridge. The boy got hold of some .22 long ammunition and when the cartridge failed to go in completely he held up the open barrel and tried to push it in with a pocket knife. It went off and the bullet lodged in the gun barrel. The shell was thrown back and entered the left cheek a half inch behind the angle of the mouth. Nothing was done for three weeks and most of the swelling had subsided when he was taken to a hospital and an incision was made inside the mouth in an attempt to locate and extract the foreign body.

This failed and I first saw him two days later with a very extensive cellulitis of his left

face and some trismus. He was sent home. Mouth irrigations and cold applications were ordered and an analgesic given. He got worse and two days later was admitted to the hospital where the same regime was continued. The second night after admission an abscess burst inside his mouth and the edema and temperature rapidly subsided. An x-ray now showed the shell of a .22 long cartridge slightly behind and above the left lower unerupted last molar. Under general anesthesia an external incision was made in the direction of the facial nerve fibers and the parotid duct. The foreign body could not be felt. Confident that it must be near, an incision was made in the masseter muscle and a large cystic space filled with sanguinopurulent material was opened. The shell lay in this. It was extracted and the cavity packed to control hemorrhage. The wound was closed with a gauze wick emerging through the skin. At first there was a noticeable muscle weakness about the angle of the mouth, but this has practically disappeared.

The American Journal of Surgery is truly independent and enters into no "entangling alliances." It publishes many papers read before the leading surgical societies of the Country, but it is *not* "the official organ" of any organization. Every manuscript is selected by the editors, as worthy of publication—nothing is published merely because "it was read at the meeting."

EDITORIALS

POST-GRADUATE EDUCATION

IT is that of a layman, purely, my interest in post-graduate medicine.

An informed layman, perhaps, since as Commissioner of Public Welfare in the largest American city for eleven years, and as Controller of the same city for four years, I have been brought into close contact with hospitals, private and public, and with the physicians employed in and attending them. But my point of view is that of a layman primarily, of the fellow who is to be treated and not the fellow who is to treat such ailments as may afflict my body and bones. I want to be sure that my doctor knows his business, that he is to treat me, when I suffer from some of the ills that afflict mankind, as a sufferer whose pains are to be mitigated, who health is to be restored and not as a specimen from

which he may learn something about pathology. In other words I want the doctor to know his job before he starts to work on it. Now, after a long and ripe experience, I want to join in a program that would give physicians the opportunity of obtaining such experience and knowledge.

It is quite natural, I suppose, that a young licentiate in medicine should desire to capitalize his knowledge as soon as possible. He has spent his years at preparatory schools and his college of medicine. He has heard his professors, attended his clinics, read his books. He has passed all his exams. He has his certificate as a doctor of medicine. He has the state license to practice. Let's go!

But every experienced physician knows

that as soon as one confronts life he finds conditions of which he never heard in his school, or which seem to him so entirely different in fact, from his academic conception of them that they call on him for original thought which should be guided by a profound and varied contact with facts. What chance has the young fellow who has his doctorial degree fresh in his consciousness and no post-graduate experience and who goes out to practice? He may go to the country where there are few hospitals, or none. He may have to learn at the cost of patients, something which he will regret deeply if he be the right kind of a man under the right kind of a doctor. He will learn, of course, but slowly. Medicine may in its rapid progress get entirely beyond him and he may become an old foggy, a frustrated man, and even descend to a form of quackery all the more offensive because he has the license of the state to practice and the knowledge that the earth will cover his mistakes.

When I was Controller, it was my business to look after the finances of the City's public hospitals, and then I found that experience as internes in these hospitals and as staff attendants was desired by most young doctors. The most ambitious minds sought them from our own city and from the whole nation. I found that Bellevue was aiding the city medical schools. Later when I became Commissioner of Public Welfare, operating directly 15,000 beds of all kinds, this phase of city hospital work became to me more apparent and most important. In view of the problems of post-graduate needs in medicine which constant contact with the members of the Committee on Public Health Relations of the New York Academy of Medicine, eminent local doctors and the leaders of the American Medical Association, the American College of Surgeons and the American Hospital Association, impressed on my mind, I felt that a vast amount of medical material in many of the great institutions of the city was going to waste, and that this waste

was at the expense of the patient. From this, I became convinced that hospitals connected with medical education gave the sick the best attention. I tried to meet this. I started post-graduate lectures and clinics in the great Kings' County group in Brooklyn, and in the Metropolitan Hospital cooperated with Flower College in a rather complete course, which the College considers to be most successful. I did my best to start them in every one of our hospitals. I tried to get a vast pathological laboratory constructed at Kings' County Hospital and a liaison established between that group and the Long Island College Hospital Medical School, but—well, there are politics in medicine as well as outside, and my efforts were nullified by unfortunate circumstances. However, my interest in post-graduate medical work is still keen and I do hope that the time will come when all the great city hospitals, public and private, will aid in making the young graduate in medicine a better man for his job of aiding suffering humanity.

I want to be of service, not alone in extending greater facilities for post-graduate work in the City of New York, but in other great medical centers of our country. There are many liberal and broad-minded men and women in rural or semi-rural communities who could not do a better turn for their neighbors and themselves, than by financing the post-graduate education of doctors that are treating and attending them. I have talked with many of the most able and conscientious of the hundreds of internes seeking to learn the reason of their aversion of residing in well-paying rural or even fairly large towns. The answer of almost all was that this would bury them and that they could not keep in touch with their profession. For the benefit of the health and lives of our people, I hope that the AMERICAN JOURNAL OF SURGERY can start and carry through a discussion, out of which we can get together and form a plan that will bring the doctor from even the outpost of civili-

zation, in touch with the latest progress in medicine and surgery.

BIRD S. COLER.

Former Commissioner Public Welfare,
City of New York.

[This communication] is worthy of unu-

sual consideration, as it gives a lay viewpoint of an important phase of Medical Education by a man who is recognized as an expert on such matters, because of his long experience as the governing head of The City Hospitals of greater New York. ED.]

GONORRHEA: A CRITIQUE*

DURING the last few years I have written and talked so much about the laboratory and clinical phases of gonorrhea that I have not the courage to bore you further with them. For this reason, and the fact that of late my mind has been turned more constantly in that direction, I have chosen to discuss the broader aspects of the matter, the relation of the disease to mankind at large and the profession of medicine in particular; to sketch conditions frankly as I think they are and to try to point out some things that must be done if the present unattractive picture is to be changed for the better. If, at times, the criticisms seem destructive I am going to ask you to bear with me for there is no wish to be offensive or unkind. At times the frankness may seem harsh but time does not permit of dressing each thought in honeyed words to soften the blow, even were it in my power to do so. The plain, blunt statement of a fact usually is more arresting and there is no subject in all of medicine in which plain talking is more needed.

That you may immediately sense the importance of the disease I shall briefly outline a few estimates of its prevalence. This would seem unnecessary to such an audience but I doubt if any of us fully realize what the disease is doing. You may question the accuracy of the figures given and they will not suffer greatly if you cut them in half.

It is estimated that from 60 to 90 per

cent of all males in large cities have gonorrhea at some time during their lives; that 20 per cent of all married men contract the disease at some time during their married lives and of these 45 per cent infect their wives; that from 40 to 60 per cent of all operations on the uterus and its adnexa are thus occasioned; that gonorrhea accounts for at least 5 per cent of all blindness. Added to this is a sum total of human misery that is staggering and, last, but perhaps not least, is an economic loss that runs into millions of dollars.

If these estimates do not strike you let me quote a few figures given in Dr. Haven Emerson's report after an exhaustive health survey of my own city, a city that I think you will agree with me is as clean as any city in the country having more than half a million people. Dr. Emerson estimated that we develop more than 159,000 new cases of gonorrhea and syphilis annually and that the incidence of gonorrhea is at least five times as great as that of syphilis. Let me go further with his figures, and remember that these figures are not idle guesses but represent months of the most careful investigation of the question from almost every angle at cost of many thousands of dollars.

He found that 45,800 of these cases are treated by recognized medical agencies and at least 114,000 have no trained medical supervision whatever. It is further brought out that 33.3 per cent of our druggists admit that they treat these

* Read before the New York Academy of Medicine, Section of Genito-Urinary Surgery, October 16, 1929.

diseases, though it is directly against the law of the commonwealth, 23.2 per cent of them refuse to commit themselves on the subject and 43.5 per cent say they send such patients to physicians or clinics. It was not possible to learn or to estimate how many were treated by quacks and charlatans. When the inquiry as to what they would do if they had a venereal disease was made of 100 individuals chosen at random in pool rooms, barber shops and other public places, a rather surprising state of affairs was shown to exist. Forty-two per cent said they would consult a druggist, 24 per cent a physician, 16 per cent a clinic, 4 per cent would use a home remedy and 14 per cent did not know what they would do.

Surely, as guardians of the public health, we have much food for thought in these figures. We cannot appease self-conceit by calling them merely local and an expression of what you are facetiously pleased to call Philadelphia somnolence. Similar conditions are being demonstrated in each of our large cities and certainly the reporting of 159,000 cases of the venereal diseases each year, in a city of 2,000,000 inhabitants, would seem to brand us as rather wide awake. No one has ever thought that the medical profession of my city is asleep, as the record throughout the years has shown it to be rather an alert body.

Let us make no mistake about it. The above conditions are national and they cry so loudly for correction that it behooves us to give them the most serious consideration. Obviously something is radically wrong when so large a proportion of that great group of diseased individuals does not even choose to consult us. The business man would call it wretched salesmanship but the fact is, insofar as gonorrhea is concerned, and most of these cases are gonorrhea, we have not even tried to sell anything. In this regard we have drifted so long that I fear the fault has become public property and in the eyes of the social-minded our profession is definitely

on the defensive. This we perhaps would do well to admit. Faults are rarely corrected until they are admitted.

Insofar as we are concerned, wherein lies the fault? Unquestionably our greatest fault in regards to gonorrhea has been a most unfortunate lack of medical interest in it and its victims. We have been so busy thinking of more attractive things that we have allowed this one to drift along bearing the heavy mosses of other years. One might appropriately borrow a term from the sociologists and call our present position one of the "Costs of Progress," for every human gain is made at some cost.

Twenty years ago we knew almost as much about gonorrhea as we do today and very few doctors thought it beneath their dignity to treat it. Some even specialized in it and called themselves genito-urinary specialists. Then some grew rather proud for such a name and the designation urologist was adopted. This was perhaps in the line of progress; but, as it grew in dignity, it grew to mean bigger and bigger things and, though it still embraced the smaller things, it gave them scant attention. There was formed a national association of urologists and about fifteen years ago this body took great pride in the fact that it put across an annual program without any papers upon the so-called venereal diseases. One cannot severely criticize this, however, for the papers on venereal diseases were of a type, as a rule, that should not have been presented before such a body.

Much of our urological progress has been due to the stimulus to scientific work given by the American Urological Association and today American urology commands the respect of the world. The lure of surgical urology, however, has relegated gonorrhea to a place of obscurity and many urologists have grown so proud that they hesitate to admit that they treat such a lowly disease; in fact, some even deny it. Surely we have progressed at a terrible human cost.

Gonorrhea either belongs to the realm of Urology or it does not. We all feel that it does and perhaps it would have fared better if our National Association had exhibited more tolerance and encouraged thought upon the subject by patiently listening to a few papers on it each year. Certainly nothing that afflicts the human race is too lowly for the physician to consider, and if we find ourselves growing too proud over our remarkable progress we can find ample reason for humility in the contemplation of that vast horde of afflicted that do not even "choose to run" in our direction but prefer the druggist and the charlatan.

Turning, then, to a consideration of things as they are, we find ourselves faced by a number of perplexing conditions that are by no means easy to surmount. We find an awakening interest upon the part of our profession on the one hand and a public that is in no sense social disease-minded on the other, all influenced by a public press giving columns to love and its roses and not daring to mention the name gonorrhea, its greatest thorn. We find genitourinary dispensaries in most of our hospitals occupying quarters that no one else wants; woefully inadequate for the numbers of patients visiting them; lacking in any possibility for privacy; so poorly manned as to compel herd treatment for the most individualistic of all diseases and totally out of sympathy with the governing boards of the hospitals, not because they dislike the staff but because they loathe the diseases treated by them.

Scientifically we are faced with an even more unfortunate state of affairs and, if we are to be honest in our analysis of what we know or do not know, we are forced to make some painful admissions. Let us make the great one first. We know little more about the disease and its treatment than we did twenty years ago and much of what we think we know will not bear too close a scrutiny. In fact there is a crying need for an entire restudy

of the disease to the end that we may discard the huge mass of misinformation that has accumulated about it. Much of what passes for science in this regard is not even good pseudo-science; often it is ridiculously erroneous. We could abandon with profit much of what we think we know about the gonococcus, for an enormous amount of it is simply not true. Our knowledge of the microscopic pathology of the disease has had little if anything added to it in thirty years. What we style "knowledge" of the immunologic aspects is a mass of contradictions. We have little knowledge of the true curative processes except that patients do get well; but we do not know how or why. When we view the clinical side of the question we encounter a maze of confusion with little uniformity of opinion or belief. And, when at least we turn our thoughts toward cure, we find ourselves in a veritable ocean of dreams. It looks as if we have neither rudder nor compass to our ship, and though we may know where port is, we often choose weird and windswept courses to reach it.

It is a great misfortune that a disease that afflicts such a large proportion of the human race should exhibit, perhaps, the most delicate immunity-balance of all diseases, for it is this feature of it that gives us our crowning perplexity. So adversely influenced is the disease by seemingly innocent things that we have always been hampered by its clinical vagaries in our efforts to evaluate properly our plans of treatment. It is only when the personal conduct of the patient is above reproach that one may differentiate surely between patient-faults and treatment-faults. Occurring as it does most commonly in those years of life when desires are strong and inhibitions halting, it is natural that it should have seemed so impossible of classification, with variations as numerous as the cases. And because of these things we have almost an endless number of plans of treatment and perhaps none of them has ever had what might be called a

scientific, well-controlled trial. Wherefore, there is urgent need for an entire restudy of these methods carried out upon patients where they are under constant observation and cared for by deeply interested physicians really familiar with the disease and the things that so quickly change the clinical picture. Lacking generally the facilities for hospitalization of gonorrheal cases, it would seem that the various branches of the governmental service, where large numbers of such patients can be readily restrained as to certain activities, might find a valuable work waiting at their doors.

So much for some of our perplexities. What are the modern trends of thought and action? One only has to question a few of that increasingly numerous group of social-minded individuals who spend their lives on the borderline between the doctor and the afflicted, to learn that they are keenly alive to the great need for action regarding the prevention and better treatment of the so-called "social diseases." Governmental agencies and social agencies within the last few years have been awakened as never before (except, perhaps, during the World War), are treading upon our heels and, unless we respond, we shall be pushed aside by the great demand for action.

We dread big business in medicine and, in this regard, we offer a golden opportunity for its entrance. Unless we as a body give the matter earnest attention we shall have duplicated in every large community just what has taken place in our second largest city. There has been built up in it an enormous institution doing, in its own way, and in competition with our profession, a thing we have failed so completely to do. And, though we may call its methods unethical and doubt the wisdom of some of the things it does, the fact remains that it is in its way filling a public need that we have allowed to arise. If it were not filling such a need it could not have the sponsors that it has.

They are too wise in the way of business to sponsor a needless thing.

It is becoming increasingly simple to interest individuals of great wealth in this phase of medicine and I am given to understand that even now one of the great "foundations" has given a kindly ear to the question. An institution in a neighboring city has been given a large fund and I am told that the venereal problem had much to do with it. I am further informed that your own city has been surveyed with this thought in mind and that the only reason why you have not an enormous institution for the treatment of these diseases, working in financial competition with you, is that you have a peculiar state law that curtails its publicity efforts. If this is true, it might be well for a committee chosen from your numbers to watch that law until such time as you so change present conditions as to make such a step on the part of big business unprofitable. Unquestionably this is the "handwriting on the wall" and, if we would save the situation we must put away petty feelings and work in harmony, for, if these things happen in one field of medicine, none will be immune against them.

If, on the other hand, an abounding humanitarianism makes us feel that as an individual, the physician has served his purpose and that the human race will be far better off when most of us seek other fields and the rest of us become cogs in some great medical institution which sells our services to whoever comes to buy, we have only to sit and wait. Wealth has scant regard for what we call medical ethics and is not willing that it should stand between us and public service.

What shall we do about it all? Apparently we have lost or have never had the confidence of an enormous number among our population. The rather obvious reasons for some of this have been previously discussed. When a business finds itself in such a predicament it tries to improve its product and it goes after

customers, from both of which moves we might learn. Certainly we must improve our product and just as certainly some form of dignified, ethical and concerted effort should be carried out to make our communities venereal disease-minded, for, unless the public is aware of the great menace of these diseases, we can hope for little in the way of greatly reducing their prevalence. With countless numbers of infected individuals throughout the land being "treated" by the druggist and the quack without any medical supervision whatever; with a medical profession not altogether alert to the seriousness of the problem; with a knowledge of the disease that has not yet reached a stage wherein there is much uniformity of procedure, a knowledge often unfortunate in the survival of treatment plans that could only prolong the infection, unquestionably we have much ground to cover.

Let us discard that sense of pseudo-niceness that makes some of us too proud to admit that we treat such a disease. If we cannot arouse an interest in the disease and in its victims, sufficiently great to make us willing to carry out the required procedures, let us be honest and not treat it at all. It is too serious a disease for makeshifts in treatment.

By the nature of things most of the preventive work must of necessity fall upon our shoulders. It must rest on the proper care of the disease when present, the proper control of those afflicted and the proper instruction of those patients whom we think we have carried on to a cure. Without the cooperation of the diseased, our efforts at cure and prevention must come to naught, and without a kindly attitude toward them we cannot gain that cooperation.

We must strive to make a better type of treatment available to the poor under conditions of privacy more nearly approaching that afforded our office patients. To do this we must entirely revise the common dispensary methods. The usual genitourinary dispensary is a gloomy,

ill-fitted place having so few physicians in attendance that the order of the day must be the greatest good to the greatest number, with privacy and individual encouragement for none. Until we can correct these conditions universally we encourage commercial exploitation of the poor.

We must in our dispensaries, at least, cooperate with the established social service agencies, for, no matter how much we may question their former activities, the fact remains that today they are, by and large, a body of specially trained individuals and without their help a genitourinary dispensary can only haltingly fulfill its great purpose.

In bringing about a general change in dispensary methods we are sure to encounter some great difficulties. We must start by convincing the hospital governing boards that they are necessary. We must make the case so strong that funds will be forthcoming to effect the necessary changes in physical equipment or we must find the funds, a thing not so difficult today as it would have been a few years ago. The data obtained by the United States Public Health Service and the American Social Hygiene Association in their various surveys give a wealth of convincing argument.

As the quickest way to bring about such an improvement and perhaps in a measure force the hand of those hospitals unwilling to join the march of progress, the suggestion has been made and, if properly carried out, I see no great fault in it, that each large city have at least one independent, model clinic for the proper treatment of venereal diseases among the poor. Such institutions should be started by the physicians and not by the laity. There should be on the governing board physicians of the highest type who have nothing to gain financially by the association. There should be associated with them laymen of such outstanding position that they have nothing to gain beyond the mental satisfaction of things done in a

worthy cause. Such a clinic should be run in cooperation with the physicians and existing hospital dispensaries, and never in competition with them, and the medical members of such a board should at all times see that nothing of a harmful and unethical nature is allowed. These centrally located institutions should have every patient interviewed by a social service registrar and should refuse to treat any patient who is financially able to pay a physician's fee. It is only by so doing that they can obtain and hold a kindly place in the scheme of things. Such a clinic should in every way strive to serve as a model to the end that existing institutions will be glad to copy its methods and it should be willing to discontinue the treatment of patients just so soon as it can be shown that existing hospital dispensaries have reached a plane rendering the model dispensary no longer necessary. The governing board, however, should continue to function as an educational medium for the public, for unless a community can be made and kept venereal disease-minded, it will soon sink back into the position from which it was only temporarily raised.

If, as is possible, you disagree with the idea of a model central clinic not belonging to any hospital but to all, you must of necessity face the evils of present conditions insofar as the treatment of the poor is concerned. These evils are glaring ones and they will not find correction until we show a lively interest in them. As has been said, the usual genitourinary dispensary is a dreary place wherein large numbers of patients must be treated by none too interested physicians while, what seems to be the world, looks on. There is neither the thought nor the possibility of privacy. Because of the number of patients and the scarcity of men willing to treat them, oral medication, in which few, if any, seriously believe, is the most common treatment. If local treatments are the order of the day they usually must be carried out by the patient

himself and their train of disabling complications usually is just what should be expected. The proper treatment of these patients in large groups is tedious and tiresome and until we find a way to remunerate the men who do it, we shall hardly correct conditions. Regret it as we may, the age of long apprenticeships in medicine has passed and our younger men cannot financially afford to treat the same things month after month unless it in some way yields an economic return.

There are, of course, many other phases of this important subject that might be dwelt upon with both interest and profit. It, however, would be kinder not to try your patience by prolonging the discussion further. It has not been my desire to be offensively critical; I have only wished to make you see conditions as they have grown to be and I cherish the hope that I may have been able to stimulate an interest in you that will transcend any hesitancy you may have had regarding this social outcast, gonorrhea, to the end that you may individually and collectively give earnest attention to the treatment and prevention of what well might be called "The Fourth Great Plague."

P. S. PELOUZE, M.D.

NOTICE

WHEN the Radiological Department was added to this Journal, it was assumed as a matter of course that the articles on radiology should be collected together under the general heading DEPARTMENT OF RADIOLOGY. However, on reflection it does not appear that there is any good reason why these articles should be so segregated. In many instances it is really difficult to decide whether a communication should be classed under the head of surgery or under radiology, although it contains radiological data and observations of great importance. Swick's paper on Intravenous Urography, published in the February number, is a radiological article of greatest impor-

tance, yet of greatest importance to surgeons; and it really deserved a more prominent place in that issue of the Journal.

So while the Radiological Department will be continued as before, beginning with this issue there will be no special heading, but the articles will be scattered through the Journal as all other articles are, there being no particular reason for having a special heading for these when there is none for other subjects.

INTERNATIONAL SOCIETY OF ORTHOPAEDIC SURGERY

AT A meeting of the Executive Committee of the International Society of Orthopaedic Surgery, held in London, February 1st, the following members were present: Sir Robert Jones of Liverpool, President; Prof. V. Putti of Bologna, Second Vice President; Dr. J. Delchef of Brussels, General Secretary; Prof. M. Maffei of Brussels, Treasurer; and Mr. Fairbank of London. At the suggestion of the French and German committees it was decided to propose at the next general assembly an increase in the membership of the Society. The next Congress of the Society will be held in Paris, October 2-4, 1930.

As a part of the program there will be two symposia. The first will be on the

subject "Treatment of Congenital Dislocation of the Hip after the age of fifteen Years." Reporters will be chosen from the United States, Germany, Great Britain and Italy. The second symposium will be on "The Treatment of Wrist Injuries" and reporters will be selected from France, Holland and Sweden.

The American committee is composed of Fred H. Albee, Chairman, William S. Baer and Henry W. Meyerding.

SAMUEL D. GROSS PRIZE

THE Samuel D. Gross Prize of the Philadelphia Academy of Surgery has been awarded by the Trustees to Dr. Emile Holman, Stanford University Hospital, San Francisco, for his Essay upon "Abnormal Arteriovenous Communications."

CORRECTION

IN the article on "Radiological Demonstrations of Pleurisy in Children" by Dr. E. Gordon Stoloff in the March Journal, the caption under Figure 7 should have appeared under Figure 9, that under Figure 8 under Figure 7 and the caption under Figure 9 should have been under Figure 8.

In the April issue the cuts on pages 852 and 853 were interchanged. The legends are alike.

Subscribers to THE AMERICAN JOURNAL OF SURGERY visiting New York City are invited to make the office of the publishers (Paul B. Hoeber, Inc., 76 Fifth Avenue, New York) their headquarters. Mail, packages or bundles may be addressed in our care. Hotel reservations will gladly be made for those advising us in advance; kindly notify us in detail as to requirements and prices. List of operations in New York hospitals on file in our office daily.

JOHANN VON MIKULICZ-RADECKI

[1850-1905]

BIOGRAPHICAL BREVITIES
"Mikulicz's Drain"

The American Journal of Surgery
N S Vol. viii, May, 1930

"MIKULICZ'S DRAIN"

JUNE of this year commemorates the twenty-fifth anniversary of the death of Johann von Mikulicz-Radecki, one of the greatest of the Continental surgeons who entered the stage prior to the age of Listerism and who lived to see surgery safely launched in the 20th century. Truly, he was a surgical giant and much of his work endures, without change, till this day.

Mikulicz was born in 1850 at Cernowicz, then in Austria. He received a liberal and thorough education at Herrmannstadt, and in 1875 was awarded the degree of doctor of medicine at Wien.

Almost immediately after graduation he entered Billroth's clinic and for six years was his assistant. From his assistantship to Billroth he went to Krakaw, where he became director and professor of surgery at the University. He continued in this position until 1888 when he was called to Königsburg to become the Director of the Clinic and Professor of Surgery. In 1890 he became professor of surgery at Breslau, which position he held until he died.

Mikulicz was a real surgeon, viewed from every angle. He had a surgical background, was a skillful technician, was unexcelled in the arts of diagnosis. His mind was of the inventive type, and he devised many new operative procedures. He was a teacher who knew how to impart knowledge to others. He did much to improve antiseptic surgery. It was he who devised the present modes of exploring the esophagus and the stomach. He was the first to treat cancer of the esophagus by resection and plastic transplantation. He introduced lateral pharyngotomy in excising malignant tumors of the tonsillar region. He was the first to use non-specific protein injections

for septic conditions of the intra-abdominal and pelvic organs. He did not know the rationale of this treatment but he observed that sometimes the patients improved clinically. He described the symmetrical inflammation of the lacrimal and salivary glands, which disease bears his name. He opened up new fields in gastric and joint surgery and devised several new operations. The operation for malignancy of the colon is named after him, as is the drain still commonly used in conditions of the abdominal cavity. He was the first to give the law that in thyroidectomy some of the gland must be left. In 1892 he collaborated in an atlas and in 1898 on a treatise on diseases of the mouth. He was one of the first to wear gloves in operative work. However, the gloves were of cotton, Halstead in America was the first to employ gloves of rubber.

Mikulicz was an accomplished musician. He earned his way through the university by money received for playing an organ from 5 until 8 A.M. He continued his musical enthusiasm throughout his life. He was a great friend of Brahms.

He had eight children, four sons and four daughters. All of his sons died except Prof. Dr. Felix von Mikulicz-Radecki of the University Frauenklinik of Berlin, who visited this country this spring and gave the writer many of the facts given here.

It is a coincidence that, having done so much operative work for the relief or cure of intestinal cancer, he should contract a malignancy of the stomach and undergo an operation from which he died, leaving a name known to surgery in every civilized country of the world, when but fifty-five years of age.

BOOKSHELF BROWSING

SURGICAL INSTRUMENTS OF THE ELLICE ISLANDS*

DONALD GILBERT KENNEDY, F.R.G.S.

VAITUPU, ELLICE ISLANDS, SOUTH SEAS

THE implements of primitive peoples have a fascination for the investigator. Sometimes one finds a specimen a purpose probably similar to that for which the first ancestors of our own implements came into being. The lancets

FIG. 1. Tapping mallet and six lancets collected by D. G. Kennedy from Vaitupu, Ellice Islands. These have been presented to Otago University Museum, Otago, N. Z.

men which is obviously the embryo from which has evolved one of our own highly specialized tools, but more often the examples are primitive collaterals developed from the material at hand to serve

herein illustrated are a good example of this type.

Throughout the islands of the Pacific the use of metals was unknown. Cutting edges were obtained from whatever ma-

* Submitted for publication, January 8, 1930.

terial was available. In the high or volcanic islands, we find knives made from obsidian. Where bamboo was available its keen edge, when split and trimmed to the shape required, was found useful for cutting material softer than itself. Thus, in surgical operations, the lancet was frequently fashioned from bamboo.

In the low islands, however, the true coral atolls, such as those of the Gilbert and Ellice Groups, the bamboo does not grow and volcanic stones are absent. One might sift the soil from end to end of each one of the twenty-five atolls in these groups without finding a trace of obsidian, flint, basalt, or any pebble or grain of sand for that matter, which is not a fragment of sea shell, sea-borne pumice or coral.

Adzes were made from fragments of the shells of large bivalves while flimsy axes for hacking off green cocoanut leaves were fashioned from sections of turtle's carapace. The edges which could be given to these materials, however, while suitable, with frequent regrinding, for adzing and chopping, were quite useless for cutting knife-fashion.

The making of incisions in surgery therefore demanded a new material and this was found in the razor-edged teeth of certain species of sharks.

The method of fashioning these primitive lancets is shown sufficiently well in the accompanying illustrations of specimens which were collected by the writer on Vaitupu, one of the Ellice Islands. Those shown in Figure 1 have been presented by the writer to the Otago University Museum, Otago, New Zealand. In Figure 1 are shown a tapping mallet, three lancets made of short, wide, shark's teeth and three of long narrow ones. Their uses will now be described.

In order to make an incision, the wooden handle was held in the operator's left hand and the point of the tooth placed lightly on the region to be incised. A sharp blow was then delivered on the handle just behind the lashing threads with the wooden mallet held by the operator

in his right hand. The tooth was thus driven into the tissue making a clean and free incision.

FIG. 2. Three lancets from Vaitupu, Ellice Islands, presented to Dr. E. W. Gudger, American Museum of Natural History.

When a long incision was required, a wide based tooth was selected (see Fig. 1, lower half). The handle was held at such an angle to the surface to be incised that when it was tapped with the mallet, only the front edge of the tooth (if that edge towards the handle is called "back") cut into the tissue. The instrument was moved forward along the line of incision being tapped with the mallet and leaving a clean cut in its wake.

Teeth of various shapes were used for different purposes and a *tufunga* (master) of this particular craft had always in his house at least one instrument of each variety. The particular purpose of the broad flat type has already been indicated.

The long type illustrated in Figure 1 was capable of making a deep narrow incision and was used for opening abscesses. The small variety shown in Figure 1, upper half, was used for blood-letting. Headache was often treated in this way, the skin being pricked at close intervals with the needle-like point tapped rapidly with the mallet as it was moved over the area of pain.

The instruments are rarely, if ever, used at the present day, the evidence of their

use, given above, being received at first hand from two old-time *tufunga*.

In reference to the making of long incisions mentioned above, in connection with the use of the broad flat tooth, it may be of interest to record an operation in which this was often required. This was the removal of a subcutaneous lipoma.

An incision was made over the tumour with the shark-tooth lancet. A fish hook was then inserted into the lipoma and the line to which this was attached was given a steady strain by an assistant while the surgeon cut away the connecting tissues

until the tumour was free. Blood was removed by another assistant who applied his mouth to the wound between strokes of the lancet.

Figure 2, a photograph of three lancets in natural size, shows in greater detail the teeth and their method of attachment (lashing) to the handle. These lancets and a tapping mallet were presented by the writer to Dr. E. W. Gudger of the American Museum of Natural History, New York City. The mallet and one lancet have been deposited in the ethnological collections of the Museum.

BOOK REVIEWS

RADIUM IN GENERAL PRACTICE. By A. James Larkin, B.Sc., M.D., D.N.B., 28 illus., N. Y., Paul B. Hoeber, 1928.

In this age when many physicians have a more or less vague and disjointed conception of the indications for, and technic of the use of, radium, a book on the subject written so one need not be a super-physicist is more than welcome.

Dr. Larkin has written a book that every physician who meets with patients who may need radium applications to improve or cure their disease, or patients the physician decide to apply radium to, should carefully read.

After a preface the book is divided into five parts. Part I takes up General Considerations. Under this chapter heading the author considers the mechanics of radium, biologic reactions, methods of application in general, general technic, contraindications to radium treatment and dangers of radium application. This chapter alone is worth the cost of many works written casually on the subject.

Part II deals with General Diseases; Part III with Gynecological Diseases. Inasmuch as the modern gynecologist has occasion to employ radium in his work, cervical cancer being treated by many with radium and not by surgery, we urge the gynecologist to study this chapter; Part IV is devoted to Miscellaneous Tumors and Carcinomata; Part V, Miscellaneous and Skin Lesions, a chapter we recommend to every surgeon and dermatologist.

There is a complete Index. All in all it is an excellent, authoritative and timely book on a subject close to the majority of the doctors of medicine.

VARICOSE VEINS with Special Reference to the Injection Treatment. Ed. 2, rev. & enl. By H. O. McPheeters, M.D., F.A.C.S. 235 pp., illus. with half-tone and line engravings. Phila., F. A. Davis Co., 1930.

The first edition of this book was sold out in five months, an indication that it surely answers a definite need. The author has revised Chapter V on "The Trendelenburg Test" which, according to his Preface, was thought not to be detailed enough in the first edition. It is a well printed book that deserves the success it has achieved.

A TEXT-BOOK ON ORTHOPEDIC SURGERY. By Willis C. Campbell, M.D., F.A.C.S. 705 pp., 507 illus. Phila., Saunders, 1930.

Another textbook on orthopedic surgery, well written, well printed and well illustrated and covering the ground in fairly complete fashion in 705 pages. As the author admits in his Preface: "Our knowledge at the present time is far from complete, and as additional information is acquired our opinion on many subjects will probably be altered." "However," says he, "an attempt has been made to give a sufficiently comprehensive classification, especially of infections of joints, bones, and tumors, to afford a clearer exposition of the more complex subjects. . . No attempt has been made to describe all known methods of treatment, but only those which, in the judgment and experience of the author, are considered to be of practical value. The essentials of modern operative methods are defined, and in many instances the technic described for a better understanding of these principles."

In this attempt the author has been success-

ful. We look for improved and enlarged reprints for many years to come.

PRACTICAL MASSAGE AND CORRECTIVE EXERCISES WITH APPLIED ANATOMY. By Hartvig Nissen. Ed. 5, Revised and Enlarged by Harry Nissen. 271 pp., 72 illus. Phila., F. A. Davis, 1929.

This is the fifth edition of a work first published in 1889. It is, as its title indicates, strictly limited to practical massage, and it lives up to its title very well indeed. It is refreshing to see a work on any phase of physiotherapy that does not entail the expenditure of thousands of dollars for apparatus. In the opinion of the reviewer much of the good of modern physiotherapy can still be attained by the proper use of corrective exercises, and the indication for its proper uses are well stated in this little book.

APPLIED PHYSIOLOGY. By Samson Wright, M.D., M.R.C.P. With Introduction by Swale Vincent, M.D., LL.D., D.Sc., F.R.S. (Ed. & Canada). Ed. 3. 590 pp., 128 illus. Humphrey Milford, Oxford Univ. Press, 1929.

With the general recognition today that physiology is the foundation stone of modern medicine, there is definite need for a book of this kind. As Dr. Vincent points out in his Introduction: "The day has gone by when a practitioner, however, modest, can afford to declare that 'he has forgotten his physiology.'" This book on applied physiology is much better adapted to the needs of the physician in active practice who wishes to review his physiology, than is the average textbook. It might well be termed the "Practitioner's Physiology."

GETTING WELL AND STAYING WELL. A Book for Tuberculous Patients, Public Health Nurses, and Doctors. By John Potts, M.D. Introduction by J. B. McKnight, M.D. Ed. 2. 221 pp. St. Louis, C. V. Mosby, 1930.

The sub-title of this volume, "A Book for Tuberculous Patients, Public Health Nurses, and Doctors," really tells the whole story. By putting this book in the hands of tuberculous patients, the doctor may simplify his work. Undoubtedly the average nurse will also profit by its study. The fact that a second edition is called for in three years is evidence that the book answers a definite purpose.

DEMONSTRATIONS OF PHYSICAL SIGNS IN CLINICAL SURGERY. Revised and Enlarged. By Hamilton Bailey, F.R.C.S. (Eng.). Ed. 2. 286 Pages, 306 illus., some col. N. Y., Wood, 1930.

The author states, "This book, founded upon demonstrations to fourth-year students,

was designed for their use." In spite of this fact, this book should be of great value to the practicing surgeon. The perusal of this book will bring to mind many a little point that has been forgotten and overlooked in active practice. While it is elementary on the face of it, the reading of this book will well repay anyone interested in careful surgical diagnosis.

A TEXT-BOOK OF PSYCHIATRY for Students and Practitioners. By D. K. Henderson, M.D. (Edinb.), F.R.F.P.S. (Glas.) & R. D. Gillespie, M.D. (Glas.), D.P.M. (Lond.) Ed. 2. 536 Pages. Humphrey Milford. Oxford Univ. Press, 1930.

"A Text-Book of Psychiatry" by Dr. Henderson and Dr. Gillespie is dedicated to Adolf Meyer, of Johns Hopkins. It is interesting to note that while the authors are Englishmen, Dr. Henderson being Physician-Superintendent of the Glasgow Royal Mental Hospital and Dr. Gillespie the Physician for Psychological Medicine at Guy's Hospital, London, both of them received their training as psychiatrists in Baltimore.

The book is thorough and up to date. The omission of references to some of the more modern American books is probably an oversight, as the text shows a thorough knowledge of modern literature. It is a comprehensive and authoritative text and reference book. The subject is here authoritatively presented in reasonable format.

PROCEDURE IN EXAMINATION OF THE LUNGS. With Especial Reference to the Diagnosis of Tuberculosis. By Arthur F. Kraetzer, M.D. With a Foreword by James Alexander Miller, M.D. 139 Pages. N. Y., Oxford Univ. Press, 1930.

Dr. Miller says in the Foreword: "Many of our text-books have made the examination of the chest far too complicated, and Dr. Kraetzer has made a real contribution in simplifying the methods involved." Not everyone will agree with this statement, but Dr. Kraetzer's little book of 125 pages (unfortunately without an Index) thoroughly covers every phase of the examination of the lungs. Anyone feeling that this subject is not sufficiently covered in the average book on physical diagnosis will find this volume of interest and of value. Probably, it is only by the publication of enthusiastic monographs of this nature that the authors of textbooks will find it possible to get their detailed information, and it will then be their job to condense and correlate with other subjects.

The medical student of today has our sympathy if he is expected to read a book on all the phases of diagnoses and treatment on which we older men needed only to read paragraphs or chapters.

THE NERVOUS CHILD. By Hector Charles Cameron, M.A., M.D. (Cantab.), F.R.C.P. (Lond.). Ed. 4. 256 Pages, 8 Plates. Humphrey Milford, Oxford Univ. Press, 1929.

The nervous child is one of the problems of the day and every physician, be he family doctor or surgeon, faces this problem at one time or another. Therefore, the first chapter alone on "Doctors, Mothers and Children" is recommended to the attention of every medical man. This chapter in itself is well worth the price of this book.

PROGRESSIVE MEDICINE. Vol. 1, March, 1930. Phila., Lea & Febiger, 1930.

The quarterly digests of the "advances, discoveries and improvements in the medical and surgical sciences," known to many of the profession under the general title, "Progressive Medicine," are too well known and worth while to need more than a casual introduction.

The latest number (March 1930) continues the high standard of previous issues. Surgery of the head, spinal cord and peripheral nerves is covered by Francis C. Grant; surgery of the thorax, including the breast and goiter, by George P. Muller; infectious diseases, including acute rheumatism, croupous pneumonia and influenza, by H. E. MacDermot; diseases of children, by John P. Caffey; rhinology, laryngology and otology, by John A. Bacher. There is an index.

We do not intend to be hypercritical and discuss every misprint or clouded statement. However, on page 63 occurs a statement which needs correction. It reads, "No discussion of anaesthesia in cranial surgery can be considered complete without reference to the recent work of Koster on the use of spinal anaesthesia . . . the statement of Koster is important that in the last 200 laparotomies

which he performed, the entire head and face were rendered insensitive to pain . . ." This probably is a mis-statement. We have looked through Koster's writings and fail to find this statement. But we did read, "In our clinical study of complete body anaesthesia which now number over 750 cases, we have not met with serious cardiac or respiratory embarrassment."

BIOGRAPHISCHES LEXIKON der hervorragenden Ärzte aller Zeiten und Völker. Unter Spezial-Redaktion von Dr. E. Gurlt und Dr. A. Wernich herausgegeben von Dr. August Hirsch. Zweite Auflage durchgesehen und ergänzt von Prof. F. Hübner, Berlin, und Prof. H. Vierordt, Tübingen. Zweite Bd. Chavet—Gyulay. Mit 64 Bildnissen, 932 Teite. Berlin, Urban & Schwarzenberg, 1930.

The second volume of the new edition of "Hirsch's Biographisches Lexikon" is now before us and runs from "Chavet to Gyulay." Like the first volume it contains much interesting material splendidly arranged.

There are 64 illustrations on 16 plates. We feel it would be better for these portraits to be put right in with the individual biographies, even at the expense of having to use a coated paper for the whole book. If the present method is continued, however, it would seem that it would be well to have a notation at the end of the biography, stating on what page the portrait will be found. As it is now, there is no way of telling from reading the biography whether there is a portrait published and one has to turn to the list of illustrations at the beginning of the volume. This is not a serious matter, but it would seem to be very simple to put in brackets an indication that a portrait has been published.

It is to be hoped that before this set is completed, there will be a geographical list of names. It would be interesting to check up how many men from any special country have done work in medicine worthy of being included in such a work.

We look forward impatiently to the completion of this unique work which is invaluable for historical references.

A CLINICAL STUDY OF THE ABDOMINAL CAVITY AND PERITONEUM

SECTION I. THE CAVITY

E. INTRAPERITONEAL FLUIDS (*Continued*)*

5. DIFFERENTIATING FREE INTRAPERITONEAL FLUIDS. Free fluids give rise to such conditions as ascites, hemoperitoneum, bile peritonitis, chylous peritonitis, urinary extravasations; and as the various liquids spread over the peritoneal membrane or accumulate to distend the abdomen, each produces a quite distinctive clinical picture.

a. Hemoperitoneum. With free blood, the clinical picture is composite in character; there is combined evidence of acute anemia, shock, and free intraperitoneal fluid. Among the signs and symptoms are pallor, syncope, thirst, air hunger, rapid pulse, lowered blood pressure, diminution in erythrocytes and increase in the leucocytes; nausea or vomiting occur and abdominal pain, either localized or generalized, is complained of; the flanks are dull, but the shift in the line of dullness occurs in a manner which is unusually sluggish; rarely, a boggy, localized palpable mass is present within the abdomen.

Factors Favoring
Bleeding

Hemoperitoneum results from direct penetrating abdominal wounds or the rupture of some intra-abdominal organ or vessel (ectopic gestation, ruptured lutein hematoma, perforation of bowel, aneurysm). Conditions in the abdomen favor a continuation of bleeding. The vessels (gastric, intestinal, mesenteric, omental, prevertebral trunks) lie in loose tissues; there is little resistance to the flow of blood into the cavity and fatal hemorrhage may arise from a surprisingly small point. Wounds or ruptures of liver and spleen bleed very rapidly, due to the vascularity and structure of these organs. More or less

* Previous installments of this book appeared as follows: January issue, p. 193; February issue, p. 459; March issue, p. 693; April issue, p. 912.

clearly defined masses, dull to percussion, sometimes form when the blood accumulates in limited regions (below the right lobe of the liver, about the spleen, in the lesser sac,

FIG. 68A.

The leucocytosis of subserous hemorrhage. (From Wright and Livingston.)

in the pelvis, within the retroperitoneal tissues). When the bleeding is of gastrointestinal origin hematemesis or melena may indicate the diagnosis.

The leucocytic curve after intraperitoneal, as after any subserous bleeding is typical.⁸² This is a very important curve, for it occurs with conditions which may readily be mistaken for acute sepsis. The peak of the curve (200–300 per cent rise) is reached in eight hours (Fig. 68b). Hence consecutive counts within this early period show a rapidly rising leucocytosis

Leucocytosis from
Subserous
Hemorrhage

The Leukocytosis Of Intraperitoneal Hemorrhage (5: Experimental Chart No. Three)

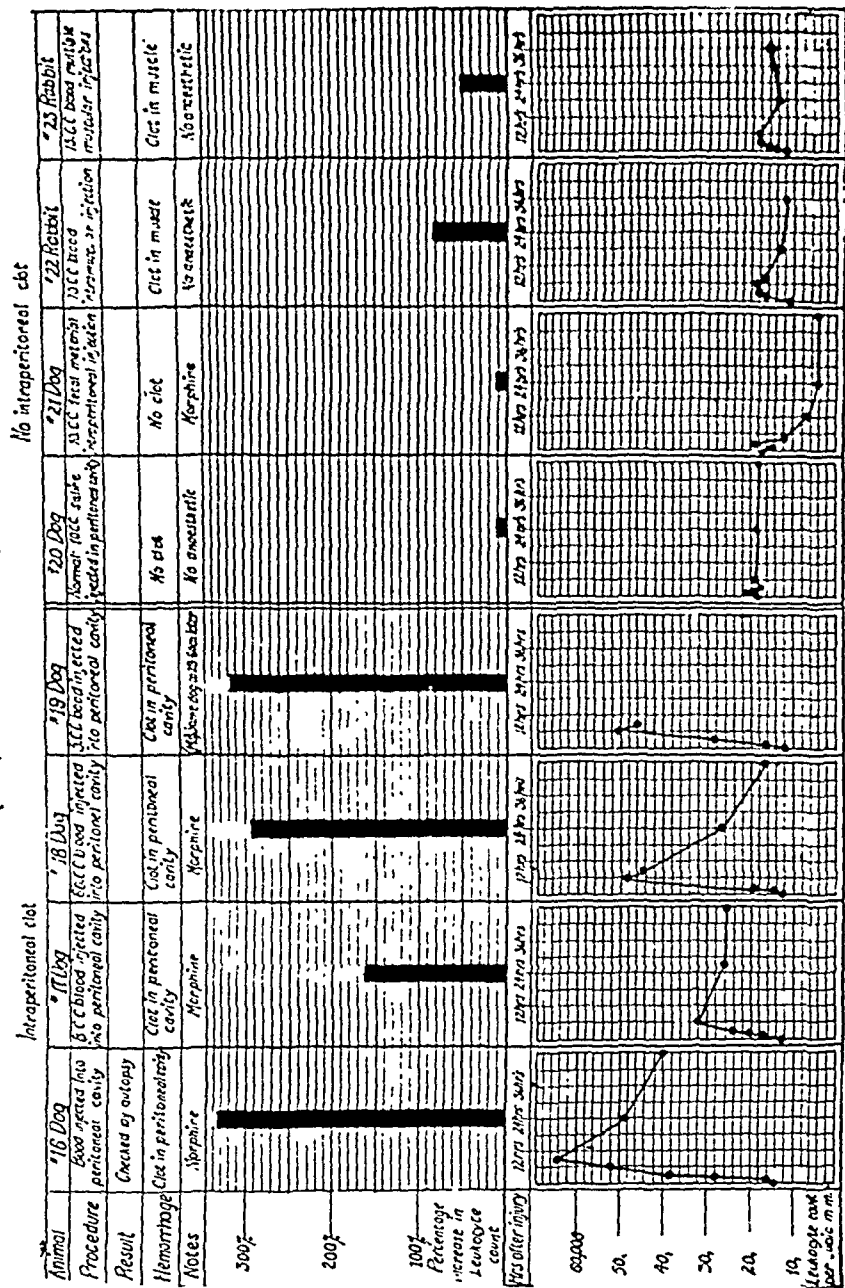

FIG. 68n.
The leucoctosis of subserous hemorrhage. (From Wright and Livingston.)

which may reach such figures as 30,000 or even 40,000 (Fig. 68a). From this early peak the count returns slowly to normal, which is reached by the fourth day unless new hemorrhages occur. The polymorphonuclear cells are both relatively and absolutely increased. This typical blood curve is unaffected by the quantity of intraperitoneal leakage or by the prompt removal of the clotted and fluid blood from the peritoneal cavity. Bleeding outside of serous cavities, regardless of the amount of blood extravasated, does not give rise to similarly marked leucocytic reactions; i.e., 2 c.c. of blood within the peritoneal cavity may produce a leucocyte rise of over 200 per cent while 200 c.c. of blood throughout the muscular and fascial planes will not double the normal count. This "leucocytosis with internal hemorrhage" is not to be confused with the so-called "leucocytosis following hemorrhage." The latter is the late, slight (20-50 per cent) leucocytic rise, which follows a severe loss of blood from the body. This compensatory leucocytosis does not reach its peak until the fourth day.

b. Bile Peritonitis (Choleperitoneum). The clinical picture with the intraperitoneal leakage of bile is that of a mild peritonitis: pain, nausea or vomiting, slight fever, distention. Rigidity is absent or slight after the initial invasion. Slight jaundice may be noted. The detection of bile in the urine or blood serum constitutes an even more delicate test than the observation of scleral discoloration. Free bile accumulates rapidly and all of the signs and symptoms mentioned in discussing the evidences of moderate amounts of free intraperitoneal fluids may be found upon examination. The bile soon becomes mixed with such serous or serofibrinous fluid as is thrown out by the peritoneum after any chemical or mechanical injury; unless infected, no pus will form. With infected bile the picture is changed to that of a severe pyogenic peritonitis.

Sterile Peritonitis

The bile may originate from the gall bladder, liver, biliary ducts, or even from the duodenum. Such leakage follows injuries (stab wounds), accidents (slipping of cystic duct

ligature after cholecystectomy) or occurs as a complication of biliary diseases (gangrene of gall bladder; erosion from stone). Although bile is very toxic and irritating when free within the peritoneal cavity, so far as the bile peritonitis alone is concerned the patient may be expected to recover if adequate surgical drainage is promptly established.

c. Chylous Ascites (Chylous peritonitis.) This is due to injury or blockage of the main abdominal lymphatics, particularly the receptaculum chyli and thoracic duct. The condition is characterized by (1) the very rapid accumulation of a large volume of milky or yellowish-white intraperitoneal fluid containing many fat globules but few cellular elements, and (2) the clinical picture of starvation and rapid emaciation. The fluid is identified as chyle only by microscopical and chemical examinations.

When there are symptoms of a disease in the neighborhood of the stomach, associated with extreme emaciation, free intraperitoneal liquid, and a tendency to copious, pale and fluid stools, a diagnosis of obliteration or rupture of the thoracic duct should be considered. Exact diagnosis depends upon study of the free fluid and the nature of the underlying lesion is usually conjectural until the time of operation or necropsy. The most common causes of chylous ascites are direct injury, filarial infection, or duct obstruction from malignant or other tumors (tuberculous glands). Fracture of the tenth thoracic vertebra has been responsible for the condition. It may also arise, the exact reason being uncertain, with the peritonitis sometimes associated with Bright's disease and leucemia. Although chylous ascites usually leads rapidly to death (70 per cent mortality), spontaneous absorption and cure have been known to occur.⁸³

An accumulation of chyle within a hernial sac is termed a chylocele; chylous ascites has been discovered as a result of the laboratory examination of fluid aspirated from a chylocele.

FIG. 69. Graphic study of some signs and symptoms caused by intestinal perforation.

1, Shoulder pain. 2, Free gas, obliterated liver dullness. 3, Altered blood pressure. 4, Umbilical pain. 5, Rapid pulse. 6, Blood count. 7, Free fluid. 8, Occult blood. 9, 10, 11, Tenderness, rigidity, dissolution of abdomen. 12, Epigastric pain. 13, Caped heart. 14, Dyspnea. 15, Subnormal temperature. 16, Pallor. 17, Pinched expression. 18, Perspiration. 19, Hiccough. 20, Vomiting. 21, Clotted blood in rectum.

Chylous vs. Chyliform Ascites

True chylous ascites is to be differentiated from pseudo-chylous or chyliform ascites in which a primarily ascitic fluid takes on a milky appearance from little understood chemical changes. Chyliform ascites is more common than true chylous ascites and the conditions must be distinguished by chemical and microscopic study of the fluid.

d. Free Enteral Contents. The clinical picture caused by intraperitoneal leakage of gastric and intestinal contents has already been discussed (see traumatic rupture of the small bowel). (See also Fig. 69.) Pneumoperitoneum and hemoperitoneum are often simultaneously present. The inability to demonstrate free fluid, however, is often a fallacious guide and should lead to no delay in operation when other evidence justifies the diagnosis of gastrointestinal perforation, since perforations are uniformly fatal unless treated by operation and each hour of delay adds to the risk. A particularly deceptive part of the clinical picture is the apparent well-being of the patient for a short period after the initial shock from the perforation has passed off.

e. Intraperitoneal Urinary Extravasation. This may result from injuries to the kidney, ureter or urinary bladder, the latter being the most common site. Bladder rupture is by no means frequent (encountered in 1 in 3000 general surgical cases) but the high mortality of this accident justifies its careful study (30 to 80 per cent mortality even under the most favorable conditions).⁸¹

The full bladder is an abdominal organ exposed to injuries (Fig. 70) while the empty bladder is a pelvic structure, protected and collapsed. Bladder rupture is always due to trauma, but the accident is favored by vesical distention, alcoholism and preexisting diseases of the vesical walls; it is often observed with fractures of the pelvis (25 per cent of patients with pelvic fractures suffer simultaneous bladder injuries). Ninety per cent of cases of bladder rupture occur in males, due to the more violent nature of their activities, also to the greater depth of the female pelvis and the interposition of the uterus between

bladder and vertebral column. The true diagnosis is often ascertained only at operation since patients suffering from rupture of the bladder are frequently in shock when first

FIG. 70. Mechanism of rupture when bladder is full and trauma is in anteroposterior direction. Intraperitoneal rupture usually occurs. (After Rouvillois and Ferron, from Campbell in *Surg. Gynec. Obst.*)

seen and but a poor history is obtainable. The evidence is usually that of rupture of some viscus and the peritoneal cavity at operation is found filled with fluid having the typical appearance and odor of urine; the bladder rent is then discovered. Preoperative evidence of bladder injury, however, includes the following: inability to void, dysuria, hematuria, exquisite local bladder tenderness, a positive catheter test (more urine drained away than could have been held within the nondistended bladder, the fluid coming back through the bladder rent from the urine-filled peritoneal cavity; more sterile solution introduced through the catheter than could be held by the bladder alone. Further preoperative evidence is furnished by a positive vesical pneumoroentgenogram (150–100 c.c. of air are injected into the bladder and roentgenograms taken; if air has passed into the peritoneal cavity it reaches the subphrenic area and pneumoperitoneum is in evidence; if it reaches the retroperitoneal spaces air crepitus may be made out and the roentgenogram shows the distribution of the air; while if the

air remains within the intact bladder the film demonstrates this fact). Again the cystoscope may reveal the rent. If the extravasation is actually intraperitoneal the symptoms are those of an irritative peritonitis. As a rule the condition of the patient does not warrant prolonged study and the possibility of associated intra-abdominal injuries (ruptures of spleen, intestine, kidney) favors prompt exploration. To await the recovery from primary shock is generally viewed as unwise since the typical course without operative intervention is a progressive and rapid decline, with prompt death. Death is due to hemorrhage, shock, associated injuries, peritonitis.

f. Ascites. The fluid most frequently found free within the peritoneal cavity is that thin, serous, or watery substance which characterizes the condition known as true ascites, abdominal dropsy or hydroperitoneum. The causes of ascites have been classified by French as follows:⁸⁵

(1) *Disease of the Peritoneum:*

Non-suppurative acute peritonitis

"Simple" chronic peritonitis

Tuberculous peritonitis

Malignant peritonitis, generally secondary to a primary growth elsewhere

Hydatid cysts in the peritoneal cavity.

(2) *Obstruction to the Main Portal Vein by:*

Non-suppurative thrombosis

Enlarged portal lymphatic glands:

Malignant

Tuberculous

Lymphadenomatous

Lymphatic leucemic

Tumors of adjacent organs, such as:

Liver

Duodenum

Pancreas

Colon

Kidney

Suprarenal capsule

Stomach

Rarities such as aneurysm of the hepatic artery.

(3) *Diseases of the Liver:*

Cirrhosis

Perihepatitis, really part of chronic simple peritonitis

| | | |
|---|---|---|
| Carcinoma Sarcoma Syphilis Hydatid disease | } | Doubtful causes if the lesions are confined to the liver; i.e., if there is ascites, it is probably not due to the carcinoma, etc., in the liver, but to simultaneous affection either of the peritoneum or of the portal lymphatic glands. |
|---|---|---|

(4) *Obstruction of the Inferior Vena Cava above the Hepatic Veins*
by:

Thrombosis
 Chronic mediastinitis
 Mediastinal growth.

(5) *Chronic Failure of the Right Heart* ("backward pressure") the result of:

Valvular disease:
 Mitral stenosis
 Mitral regurgitation
 Aortic stenosis or regurgitation with secondary mitral regurgitation:
 Rheumatic or syphilitic
 Congenital pulmonary stenosis (rarely)

Chronic myocardial affections:

| | |
|----------------------|-------------------------|
| Fatty degeneration | Fibroid heart |
| Fatty infiltration | Primary alcoholic heart |
| Fatty superposition | |
| Adherent pericardium | |

Chronic lung affections, especially:

| | | |
|---|---|----------------------|
| Emphysema Recurrent bronchitis Fibroid lung | } | Generally associated |
|---|---|----------------------|

Chronic high blood pressure:

Red granular contracted kidneys
 Pale granular contracted kidneys
 Arteriosclerosis.

(6) *Bright's Disease*. In Bright's disease ascites may be caused in at least four different ways, namely, as the result of:

Part of a general dropsy

Acute peritonitis

Chronic peritonitis

Secondary to hypertrophy and dilatation of the heart, followed by failure of compensation.

(7) *Severe Anemias*, in which the ascites is usually the result of acute, subacute, or chronic intercurrent peritonitis, as in:

Splenomedullary leucemia

Splenic anemia

Lymphatic leucemia

Pernicious anemia

Hodgkin's disease

Aplastic anemia

Pseudo-leucemia infantum

Malaria.

6. A CLINICAL CONSIDERATION OF ASCITES. Ascites is always of serious import. This holds true whether the cause be medical or surgical, local or general. The condition implies either an extensive irritation of the peritoneal membrane itself or a severe interference with the circulatory system. The most common cause of ascites is heart disease; next in order come renal affections. The chief local or intra-abdominal causes are: (1) cirrhosis of the liver, (2) tuberculous peritonitis, (3) malignant peritonitis, and (4) other tumefactions which press upon the great vessels.

a. Ascites Due to Cardiac Disorders. Swelling and edema of the legs almost always precede the abdominal dropsy; the ascites is but part of a generalized edema which may include even the abdominal walls. The right heart is most often involved; the liberation of free fluid is due to a backpressure in the vessels (a transudate). A history of rheumatism is frequently obtained and the physical signs of mitral disease observed. The cardiac origin of the ascites is further indicated by irregular and rapid pulse, dyspnea or orthopnea, cardiac enlargement, precordial distress, enlarged and often pulsating liver. Forty per cent of cases showing a quart or more of ascitic fluid at autopsy have had heart disease as the cause of the ascitic accumulation.⁸⁶

b. Ascites Due to Renal Disorders. The usual condition present is chronic parenchymatous nephritis or Bright's disease. In this condition the ascitic fluid is but part of a general anasarca and it is proportionate to the accumulation of fluids throughout the subcutaneous tissues. The urinary findings include a scanty output, albumin and casts. Kidney function is found to be lowered and the blood urea high. Albuminuric retinitis may be present. Pouches are to be seen beneath the eyes; the patient may complain of headache, nausea or vomiting. The arterial tension is raised with accentuation of the aortic second sound. Cardiac and arterial disorders (myocarditis, arteriosclerosis) often coexist with the renal disorder.

c. Ascites Due to Severe Anemias. The hydroperitoneum occurs late in the course of the disease at a time when the diagnosis has as a rule already been established through the blood picture and associated evidence.

d. Ascites from Cirrhosis of the Liver. With cirrhosis ascites is a late manifestation. There is usually a history of alcoholism, hematemesis, melena, dyspepsia, jaundice. The spleen is frequently palpable. The patient has an hepatic facies. Dilated venules may be seen along the hepatic margins and over the abdominal wall.

e. Ascites with Tuberculosis of the Peritoneum. This may occur at any age; the greatest number of cases are found in the second and third decades of life. Tuberculosis is the most common cause of hydroperitoneum in children and in young women. Tuberculous peritonitis is usually secondary to tuberculous lesions elsewhere, notably in lymph glands, joints, bones or kidneys: the majority of cases are due to the bovine type of organism. A family history of tuberculosis is suggestive evidence and a personal history of a cervical adenopathy, pleurisy with effusion, chronic bone or joint disease or the discovery of a concomitant tuberculous lesion constitutes strong presumptive evidence that the ascites is excited by the tubercle bacillus. Aside from the involvement of the peritoneal

cavity as a part of a miliary tuberculosis, the following three varieties of tuberculous peritonitis are recognized: (1) the ascitic form, (2) the locular form, and (3) the fibroadhesive form. Of these the first variety is characterized by the presence of free fluid (68 per cent) and the second by encapsulated fluid (23 per cent). The condition may be symptom-free and be only accidentally discovered at operation or autopsy, but more commonly there are vague gastrointestinal complaints (anorexia, constipation alternating with diarrhea, nausea, irregular colics and pains throughout the abdomen), often associated with clinical evidences of infection by the tubercle bacillus (afternoon temperature, night sweats, general malaise). The physical signs are those of free or encapsulated intraperitoneal fluid with or without associated indefinite nodular or patchy masses throughout the belly. The abdomen may have a typically doughy feeling, that is, yield a sensation of boggy resistance. The infiltrated and chronically inflamed omentum and mesentery are shortened and retracted. The omentum itself tends to be pulled upward into a thickened roll lying transverse to the long axis of the cavity and somewhat to the left of the midline along its attachment to the transverse colon and greater gastric curvature; this often is plainly felt through the abdominal wall.

Ascites from
Chronic Peritoneal
Inflammations

Toma's sign, intended as a test in differentiating between inflammatory and non-inflammatory ascites, is based upon the shortening of the mesentery with chronic inflammations, drawing the intestinal loops to the right side of the abdominal cavity; as the patient lies upon his back there is tympany on the right (clumping of loops of small bowel) and dullness on the left (ascitic fluid) (Fig. 71). With non-inflammatory ascites, the intestines being unretracted, the distribution of the fluid is more uniform and the intestinal coils tend to float to a central location. The umbilicus, though normal in most instances, will bulge if the fluid becomes great in quantity, be thickened when multiple miliary or conglomerate tubercles exist at this point, be reddened or dusky with chronic conges-

tion due to rerouting of venous blood when there is a partial obstruction to the central vessels, or be the site of peritoneal or intestinal fistula formation from spontaneous rupture

FIG. 71. Ascites due to chronic inflammation of the peritoneal membrane.

A. Showing retraction of mesentery pulling coils of small intestine upwards and to the right; retraction of great omentum forming a transverse roll or mass; free fluid fills the left lower quadrant and pelvis.

occurring at this weakest and thinnest point in the abdominal walls.

The diagnosis of tuberculous peritonitis, made upon the presumptive evidence of the history and physical findings, may be established by the microscopical examination of excised pathological tissue, by seeing the typical miliary tubercles at operation or by guinea-pig inoculation of the intra-peritoneal fluid.

f. Ascites with Malignant Peritonitis. Cancerous disease of the peritoneum usually occurs in patients over forty; the quantity of fluid may be large and as a rule is blood stained;

FIG. 72. Transcelomic malignant transplants, showing nodules of malignant tissue which have gravitated to the lowest portions of the peritoneal cavity and may be palpated through the rectal wall.

rapid emaciation and cachexia are the rule. Multiple nodules of characteristic consistency are frequently palpable; these may exist at any point but a favorite site is at the umbilicus where the disease has spread through extension along the falciform or round ligaments of the liver, the urachus or the obliterated

hypogastric arteries (lateral umbilical ligaments). Gravity plays a part in the transcelomic implantation of free cell clusters, thus frequent sites are the perirectal reflections of peritoneum, (causing firm nodules palpable through the rectal wall), the tunica vaginalis (giving rise to irreducible scrotal masses associated with a reducible or irreducible inguinal hernia); and the ovaries, which often lie upon the most dependent pouches of peritoneum. (See Fig. 72.) Primary cancer of the peritoneum is rare; the primary nodules which cause the secondary peritonitis should be sought, especially in the stomach, rectum, breast, uterus, ovaries, prostate and pancreas. Rectal digital and sigmoidoscopic examinations should routinely be made and the vaginal examination should not be omitted in the female. Enlarged lymph glands: pubic, inguinal superficial abdominal, supraclavicular (the so-called Virchow-Troisier gland on the left side) may be studied microscopically for the identification of the type of tissue of the primary growth. The worn, drawn, anxious facies, and the emaciation about the head, chest and upper extremities, associated in the middle-aged patient with a protuberant belly containing multiple hard nodules, present a quite typical clinical picture.

The Virchow-Troisier Glands

g. *Ascites from Pressure upon Abdominal Vessels.* In addition to the tumefactions of malignant and tuberculous peritonitis there are numerous other swellings and growths which produce back pressure in the great veins of the abdomen (the iliac and hepatic veins; the portal vein and its important radicals; the inferior vena cava). Among these are carcinomata of the liver, pancreas, and biliary adnexa; enlarged lymph glands, Hodgkin's disease, etc.; ecchynococcus cysts; retroperitoneal carcinomata or teratomata. These conditions are individually studied elsewhere. There is little that is characteristic about the ascites which they produce and the diagnosis usually is arrived at only by exclusion or is not made with precision until the time of operation or post-mortem examination.

General Clinical Rules. The following represent a few broad generalizations relative to ascites and the differentiation of its many causes.⁸⁷⁻⁹⁰

When edema and swelling of the legs precede the onset of ascites, heart failure is the most likely cause of the condition.

Ascites which is but part of a general anasarca with involvement not only of the abdomen and lower extremities, but also of the other body cavities, upper extremities, face, and even scalp, is generally due to renal disorders, notably acute Bright's disease. General edema associated with albuminuria points to renal disease as the cause of the ascites.

If jaundice is associated with ascites it points to some form of portal obstruction as the cause (most often to cirrhosis or malignancy of the liver).

If ascites is the only fluid accumulation present in the patient, if, although there is also swelling and edema of the legs, the ascites is known to have appeared first, or if the ascites is out of proportion to dropsy elsewhere, it is almost certainly due to some local or intra-abdominal cause, either some form of peritonitis, portal obstruction by a thrombus, pressure on the portal vein, or to cirrhosis of the liver.

If jaundice coexists, a slight degree suggests cirrhosis of the liver, an intense jaundice, malignancy.

A history or the manifestations of syphilis point to this form of liver affection; a history or evidences of alcoholism point to cirrhosis.

An ascites which has recurred after repeated tapplings may be due to cirrhosis of the liver but is most often due to chronic hypertrophic peritonitis.

Ascites associated with multiple abdominal tumors suggests tuberculous or malignant peritonitis.

The evidence of a malignant growth elsewhere makes the diagnosis of malignant peritonitis almost certain.

Enlarged glands above the left clavicle point to malignant disease.

⁸⁷ A. J. S., n. s. Vol. VIII, No. 5, p. 1126

In children and young women tuberculous peritonitis is most common; in males over forty cirrhosis of the liver, chronic peritonitis, and cancer should first be thought of.

Persistent fever, the presence of old scars in the neck, or a concomitant pleurisy or known tuberculous lesion make tuberculous peritonitis the probable cause of the ascites.

F. PRESSURE VARIATIONS WITHIN THE ABDOMEN

The expression intra-abdominal pressure is frequently encountered in surgical literature. The term is routinely employed in discussions on peritonitis, ascites, pneumoperitoneum, visceroptosis and intestinal obstruction. But no matter how casually intra-abdominal pressure is referred to, there always remains a certain vagueness as to the precise meaning of the term and specific figures as to the actual pressure or pressures present are difficult to find. The statement may be read that intra-abdominal pressure is always negative.⁹¹ Similarly dogmatic assertions may be found that it is always positive.⁹² At times it is recorded that a negative and a positive pressure simultaneously exist within the abdomen;⁹³ at others it is written that such coexisting differences in pressure within a single space are obviously impossible. In general, the impression seems widespread (because of a similarity of terms) that intra-abdominal pressure, in some indefinite way, is analagous in meaning to the well-understood term intrathoracic pressure.

Confusion concerning Pressures

This ill-defined status of the subject may be explained by the fact that pressures within the abdomen depend upon many factors. Intra-abdominal pressure, as will later be made apparent, represents a complicated problem. The forces at work are numerous; and the combinations and inter-reactions of these forces are complex. Since the pressures themselves are variable it is not surprising that statements concerning them should also vary. Even the interpretation of manometer readings, because of the variables, proves a difficult matter. Authors in describing conditions which prevail within limited regions of the abdomen or which exist in prescribed circumstances have, at times, so extended their

The Variables

statements and so generalized, that considerable confusing and conflicting data have accumulated. As is the case with any problem involving variables, accuracy is attained only as each variable factor is taken into consideration; generalizations prove misleading.

The Clinician's
Interest in Pres-
sures

The present aim in studying pressure conditions within the abdomen is to deal solely with clinical aspects of the subject. It seems essential that the clinician attempt some correlation of the conflicting statements of surgical literature. In order to recognize pathological increases or decreases in pressures and to search intelligently for their causes, a clear understanding is requisite of what constitutes the normal. Effective treatment as well as accurate diagnosis is dependent upon a thorough knowledge of the forces at work.

Methods for Study

In contrast to the frequency with which this term intra-abdominal pressure appears in surgical writings, little or no reference to the subject is found in textbooks on physiology. These source books on human function offer little aid. While they uniformly define and describe intrathoracic pressure, they give no similar definitions or discussions on intra-abdominal pressure. The subject must be studied, then, first, through a comparison of abdomen and thorax and, second, through an analysis of certain well-understood clinical observations.

Intrathoracic Pressure. Within the pleural cavities the pressure is subatmospheric. This relative negativity is said to be developmental in origin, arising from the more rapid growth of the chest wall than of the lung tissue and from the down-growth during embryonic life of the diaphragm. This negative pressure is maintained by the rigid walls of the thorax which prevent the atmosphere from forcing the parietes inward to equalize pressures within and without.³⁴ If the ribs are removed or the chest opened, the negativity is diminished or equalized and the lungs collapse, due to their elasticity. During normal inspiration the thoracic cage is enlarged, increasing the relative negativity within the pleural cavity, and the outside pressure then forces air into the lungs until the limits of their distensibility are reached (Fig. 73). During the expiratory phase of the

respiratory cycle the weight of the chest (gravity) and the elasticity of the lungs (tension), combine to force the tidal air outward.

FIG. 73. Intrapleural negativity. The subatmospheric pressure within the potential pleural cavities is increased (greater negativity) as the diaphragm (1) moves downward and as the thoracic cage (2) is further enlarged by movements of the intercostal muscles and ribs; air is then forced into the lungs (3) by the pressure of the atmosphere.

It must be obvious that within the abdomen no similar marked and generalized negativity is possible, for the abdominal walls are muscular and contain no bony framework capable of resisting the force of the atmosphere. As pointed out, the definitions of the word chest (a box) and belly (a bag) imply fundamental differences in structure and behavior of the upper and the lower portions of the body wall. *Normally, then, the general pressure within the abdomen must tend to equal rather than to be above or below that of the atmosphere; the muscular wall must tend to be driven passively inward when outside pressure is the greater (scaphoid abdomen) and*

The Non-rigid
Walls of the
Abdomen

Muscular Tonicity

to be driven outward when inside pressure is greater (abdominal distention from fat, fluids, flatus, feces, fetuses: see preceding chapter). Yet the problem does not end here, for the muscular walls are not simply passive structures but possess tonicity; the walls are not only acted upon by pressures, but through alterations in their tonicity they may themselves play an important part in *producing* pressure-changes; the muscles are in reflex connection with many parts of the body and by reflex contractions, pressures are increased (cough) and by reflex relaxations, pressures may be relieved (see enteroabdominal reflex); the muscles of the abdomen (those of the roof, floor and walls) may act in unison, or separate muscle groups may act separately, some being opposed to others. Again, gravity plays an important role in determining local pressure conditions; the cavity is filled with organs having various and varying specific gravities, and these viscera press with varying degrees of force (static pressure) in various regions; body posture plays a part in determining where and how such static pressures will be exerted (a state of affairs which does not exist within the thorax). Still again, the hollow organs (bladder, stomach, intestines) possess intrinsic pressures of their own (intraluminary or intravisceral pressures); and any pressure change at one point in the abdomen must immediately be compensated for by resultant or secondary changes elsewhere (Fig. 74). It is apparent, then, that the problem of intra-abdominal pressure is by no means simple. The term may mean much or little and be used accurately or erroneously, according to the care with which the constantly changing intra-abdominal conditions are interpreted.

Static Pressures
(Gravity)Intraluminary
Pressures

Adhering to the practical purpose of discussing only clinical aspects of the subject, attention will be directed to some of the individual forces at work.

I. EFFECTS OF THE MUSCULAR WALLS. The distensibility of the abdominal walls proves to be a compensatory mechanism of great value. Since the cavity can enlarge, any actual pressure-

increase within may be delayed, diminished or prevented. When a plaster-of-Paris jacket has been applied around the abdomen, doing away with distensibility, any marked increase

The Plaster Jacket
and the "Dinner-
Pad"

FIG. 74. Showing abdomen completely filled with viscera. Any pressure change at one point must be compensated for by an immediate resultant or secondary change elsewhere within the cavity. (From Edinburgh Stereoscopic Anatomy).

in intra-abdominal pressure is quickly followed by severe and alarming symptoms.⁹⁵ These are chiefly due to an interference with respirations through upward displacement of the diaphragm and to circulatory embarrassment through displacement of the heart or interference with the supply of venous blood returning through the inferior vena cava. It is well-known, clinically, that in applying a plaster jacket ample space must be left over the anterior abdominal wall, if these unpleasant and dangerous sequelae are to be avoided (Fig. 75). Such a space is created by placing a so-called "dinner-pad" of folded towels over the anterior abdominal wall as the plaster is applied and subsequently removing the towels from the lower margin of the cast, thus leaving a space between jacket and

skin. This pad may be omitted if the patient has partaken of a hearty meal just before the coat is applied.

Not only are alarming symptoms sometimes caused by

FIG. 75. Abduction plaster-of-Paris splint. Note the soft pad situated beneath the plaster over the anterior abdominal wall. (From Moorhead's Traumatic Surgery, Saunders.)

The Sudden Release of Intra-abdominal Pressure

marked increases in the general intra-abdominal pressure but dangerous results may also attend the too sudden release of such an increased pressure, particularly where this has been of long duration. Thus the drainage or removal of a large ovarian cyst may suddenly be followed by an overfilling of the relaxed abdominal veins with consequent partial emptying of the heart, followed by cardiac failure. To avoid this accident, an assistant should be assigned during the operation, to the task of maintaining direct pressure upon the abdominal walls.⁹⁶ To this end the assistant, with his hands spread out, should firmly

A

B

FIG. 76.

A. Location and length of the incision for tapping the cyst immediately before removal. Such tapping is occasionally advisable, in cases where the tumor is large and interferes with respiration so much as to necessitate beginning the operation under local anesthesia.

B. Tapping the cyst: Note how assistant maintains a continuous pressure on the abdominal walls as the fluid is being withdrawn. (From Crossen's *Operative Gynecology*, Mosby).

press upon the external abdominal walls from the instant the tumor is delivered (Fig. 76). This positive external pressure should be continued until a firm binder can be applied over a large pad of cotton, and thus from the completion of the operation the abdomen may be supported until the vascular system has become stabilized. Similarly, care must be exercised in performing an abdominal paracentesis that pressure-relief is not too sudden.⁹⁷

The Scaphoid Abdomen

The scaphoid or navicular abdomen illustrates a passive collapse of the abdominal wall from inadequate opposition to the constant inward pressure of the atmosphere (approximately 15 lbs. to the square inch). Such abdominal retraction follows a severe reduction of the general intra-abdominal pressure, for example that following starvation, with the marked loss of weight in advanced carcinoma. The abdominal walls appear as though pushed inward by a huge fist. Muscular action could not explain this retraction for the scaphoid abdomen is usually found upon palpation to be soft, and were this shape simply due to a passive in-falling of the walls from the action of gravity as the patient assumes the dorsal decubitus, they would tend in a similar manner to fall flaccidly and passively outward when the erect posture was assumed. This, however, does not occur and the boat or bow-shape is maintained, in all positions, by the inward force of the atmosphere.

Contraction of the Walls

A simultaneous contraction of all of the muscles of the abdominal walls must cause a temporary increase in the general intra-abdominal pressure, quite regardless of what that pressure might have been before such contractions took place. As the pelvic floor is drawn upward, the anterior wall inward, and the diaphragm downward, aid is given to such acts as those of parturition and defecation. This action is enhanced by closure of the glottis. During the second stage of labor the abdominal pressure is a powerful auxiliary. "During an expulsion pain the woman closes the glottis and makes a powerful bearing down effort. She forces down the diaphragm and

Parturition

contracts the recti, the obliqui, and the muscles of the flanks. There is now a great increase of the intra-abdominal pressure which, obeying the law, is transmitted equally in all directions,

FIG. 77. The muscles of the abdominal walls acting as "auxiliaries" during the second stage of labor. "Intra-abdominal" pressure is added to the intrauterine pressure, aiding in the act of expelling the uterine contents. (Modified after DeLee.)

1. The downward movement of the diaphragm.
2. The inward movement of the abdominal walls.
3. Contraction of the uterine walls

the uterus receiving its share (Fig. 77). It is easy to see how the abdominal pressure is simply added to the intrauterine

pressure, resulting in increased general intrauterine pressure."⁹⁸

McBurney and the
Cough Impulse

Sudden voluntary increases in intra-abdominal pressure often prove of aid in diagnosis. The value of the cough impulse in the examination for inguinal hernia is well known. McBurney also made use of such a pressure increase in his test for acute appendicitis. In an original article, describing his point of maximal tenderness he wrote:⁹⁹ "I do not mean a tenderness elicited by pressing the entire hand into the right lower quadrant, but one which is definitely greatest at the point described, perhaps no greater an area than the tip of the index finger, where pain on pressure is most marked, particularly as the patient coughs." This voluntary increase in pressure was also used by Murphy in his method of examination for acute diseases of the gall bladder. The so-called "deep grip palpation test" which elicits the objective sign known as "Murphy's expiratory grunt" makes use of a steady pressure against the gall bladder, but relies upon the diaphragm to tell the story. The test is made as follows:¹⁰⁰ "standing directly behind the patient, providing the patient is well enough to assume the upright position, (while if not the examiner reaches over the recumbent patient from the head) the right hand of the examiner curls up under the right costal arch at the tip of the ninth cartilage; the patient is requested to take a deep breath and at the end of the expiration the examining finger seeks the gall bladder area and fixes it from beneath; the diaphragm, descending from above with the beginning inspiration, brings down the liver and gall bladder, and if the cholecystitis of cholelithic obstruction is present, the descent is checked suddenly with an accompanying groan from the patient. For the diaphragm, acting as a great piston of respiration, forces the distended, inflamed or congested gall bladder downward upon the firmly fixed hand, and the result is an abrupt cessation of the inspiratory act" (Fig. 78).

Murphy's Expira-
tory Grunt

Aids to Palpation

Voluntary contraction of the diaphragm with deep inspiration or coughing, may also be used in detecting indefinite tumor

masses which tend to slip away from the examining fingers into the depths of the upper abdomen. Here, the palpating hands upon the anterior abdominal wall are held motionless while the

FIG. 78. "Deep-grip palpation." (From Keen's Surgery, Saunders.)

patient is asked to take a deep inspiration; thereupon the diaphragm, acting as though it were a huge internal hand, forces the mass downward against the examining fingers. This method of utilizing the diaphragmatic contraction may be combined with a use of gravity, carrying out the maneuver with the patient in the knee- elbow position.¹⁰¹ Thus, as gravity carries the mass forward and the diaphragm forces it downward the examiner may often feel and definitely delimit a tumor, where before he had only a vague impression as to its existence. Still another use of voluntary muscular contraction for diagnosis may be demonstrated by the ease with which

weaknesses of the anterior abdominal wall may be seen and felt as the patient contracts the diaphragm, recti, and associated muscles in attempting to change from the supine to the sitting posture without the aid of his hands. The patient, it will be noted, closes the glottis and contracts the diaphragm during the effort to arise.

Dyspnea from
Abdominal Dis-
orders

When a pathological increase in the intra-abdominal pressure is associated with rigidity of the abdominal walls, any increase in abdominal capacity must be made at the expense of thoracic capacity, through an elevation of the diaphragm. Such a diaphragmatic elevation promptly gives rise to dyspnea or circulatory embarrassment. Because of the muscular rigidity present, inflammatory distentions give rise to pressure symptoms earlier than do those of purely toxic origin (where the walls may remain relaxed).

Certain mental defectives and neurotics may display in an interesting fashion the reciprocal relationship which exists between the diaphragm and the muscles of the anterior abdominal wall: By maintaining the diaphragm in a condition of spastic fixation, then simultaneously relaxing the anterior abdominal muscles, these patients are able to create the appearance of being tremendously distended (an hysterical tumor).¹⁰² The administration of an anesthetic causes this "mass" to disappear immediately (phantom tumor). The swallowing of quantities of air (aerophagia) serves to enhance the tumefaction of the abdomen.

A Phantom Tumor

Still another example of an alteration in pressure due to changes in muscle tonicity is the effect upon the abdominal circumference of the ingestion of food. When food enters the enteric canal the intra-abdominal content is necessarily increased. To prevent this from causing an undue change in the actual intra-abdominal pressure, the abdominal walls become relaxed, through their reflex connections with the intestinal mucosa.¹⁰³ Such a reflex relaxation of the muscles may be experimentally demonstrated through the distention of balloons which have been placed within the enteric canal.

It is this reflex (entero-abdominal or alimentary reflex) at least in part, which causes the loosening of belts after meals. The change in the abdominal circumference is often out of all proportion to the amount of food ingested. An abnormally active reflex may give rise to "bloating" immediately after the taking of even a glass of water, a cracker or other substance of small bulk.

The Entero-
Abdominal Reflex

It has been shown that the injection of a definite amount of air or fluid into the peritoneal cavity causes a rise in the systolic blood pressure, while the injection of a similar amount of the same substance into the enteric tract is not followed by a similar rise in pressure. An explanation of this observation, which would seem most puzzling since the same amount of the same substance placed within the same space (abdomen) acts so differently according to the site of the injection, is offered by this enteroabdominal reflex which accounts for the relaxation of the abdominal wall, thus preventing any marked increase in the intra-abdominal pressure, when the increased bulk occurs in the intestinal lumen (simulating normal eating).¹⁰⁴

abdominal Pres-
sure

2. ABDOMINAL EFFECTS OF THE INTRAPLEURAL NEGATIVITY.¹ It has thus far been pointed out that the abdomen, a muscular sac exposed constantly to the action of the atmosphere, must tend to have a pressure which is approximately equal to that of the atmosphere itself; that when conditions arise which would otherwise increase the intra-abdominal pressure (paralytic ileus; excessive fat; ascites; tuberculous peritonitis) the muscle walls passively belly outward in such a fashion as to reduce the actual pressure within, and that when conditions arise which might otherwise cause a decrease in intra-abdominal pressure (diarrhea; dehydration; starvation; excessive loss of fat) the muscular walls are pushed inward (scaphoid abdomen) in such a fashion as again to diminish the actual change of pressure within the abdomen; that, however, by an active and simultaneous contraction of all the muscular walls the general intra-abdominal pressure may

suddenly be made to increase; but, upon the other hand, that there is no mechanism by which these muscular walls are capable of creating a generalized and sustained pressure which

FIG. 79. Note the dome-shape of the diaphragm.

is below that of the atmosphere (a subatmospheric pressure). Notwithstanding these facts, there is one region within the abdomen in which a subatmospheric pressure is known to be normally present, i.e., the region immediately below the diaphragm. This negative pressure within the upper peritoneal cavity may be explained by the proximity of abdomen and thorax; it is a borrowed or reflected negativity; one which depends upon conditions present within the thorax, not upon the abdomen itself.

A Reflected Negativity

The abdomen is separated from the thorax only by a non-rigid partition. The dome shape of the diaphragm demonstrates the upward pull created by the subatmospheric pressure within the pleural cavities. The diaphragm does not gain its upward curvature through being suspended from above by thoracic structures. This must be apparent, since nothing pierces or is attached to the diaphragm at the points of greatest elevation (domes.) (Fig. 79.) Again, if the diaphragm were suspended from above, its normal excursions could not be made. It must be equally obvious that the diaphragm is not pushed upward from below, for when all abdominal organs have been removed (autopsy), the upward curvature remains. That the diaphragm is sucked upward by the subatmospheric pressure within the pleural sacs is demonstrated by the even higher levels to which the midriff ascends after a phrenic nerve has been paralyzed (eventration). The thoracic lifting effect may be still better shown as follows: suspend a cadaver in an upright position; observe the levels of the diaphragmatic domes and of the abdominal viscera; then open one of the pleural sacs, allowing an equalization of pressures; observe that the domes of the diaphragm, and also the abdominal organs, descend as air is admitted to the thorax.¹⁰⁵

The Dome Shape
of the Diaphragm

The same force which draws the diaphragm, upward, also exerts an upward pull upon the movable viscera of the abdomen. Thus, when a weakness occurs in the midriff, some movable organs of the upper abdomen actually enter the thorax. Thoracic suction is demonstrated by the fact, already referred to, that when the reduction of these herniated organs proves difficult or impossible from the abdominal side, the mere opening of the pleural cavity will often result in an easy or even spontaneous replacement of the viscera (the suction action overcome).

The Upward Pull
of the Thorax

An important result of the negative pressure within the upper peritoneal cavity is that after perforation has occurred in some air-containing viscus, the free air which accumulates in the peritoneal cavity travels upward to the subdiaphrag-

**Obliterated Liver
Dullness**

matic region. Even small amounts of gas tend to cause an early diminution or loss of liver dullness. The promptness and frequency with which shoulder pain is observed in the presence of free fluid or gas within the abdomen, demonstrates a subdiaphragmatic negativity. This early irritation of the central portion of the under surface of the diaphragm (with its attendant shoulder pain) often occurs even when the free substances originate at pelvic levels. Obliterated liver dullness from enteric perforations (Clark's sign) is best observed in the midaxilla.^{106*}

**Respiratory In-
creases in the
Abdominal Cir-
cumference**

3. EFFECTS OF THORACIC MOVEMENTS. Contrary to what might be expected, the negativity within the upper peritoneal cavity is greater during inspiration than during expiration.¹⁰⁵ It might seem reasonable, upon superficial consideration, to assume that as the diaphragm moves downward (inspiration) the pressure within the abdomen must, of necessity, be increased. Yet manometer readings show that normally the negative pressure below the diaphragm is greatest during the inspiratory phase of the respiratory cycle, and that the greater the depth of thoracic breathing the greater the upper abdominal negativity during inspiration. This is true because the descent of the diaphragm is not the only, nor at times the most important, accompaniment of inspiration. It may be observed that in addition the diameter of the lower thorax (upper abdomen) undergoes an increase during the inspiratory act (Fig. 80). The fact that the abdomen extends upward so far within the thoracic cage (see midriff; roof of abdominal cavity) and that the upper abdomen is covered by ribs and thoracic walls, makes it inevitable that pressures within the upper abdomen should be markedly effected by movements of the thoracic cage. This increased abdominal circumference may more than equal the effect on pressure of the descent of the diaphragm. As might be expected, this effect of thoracic movements varies

* Although this sign is present in but a minority of cases its value, when present is great. It has been said (Cope): "If in any acute abdominal case distinct resonance be obtained over the liver in the midaxillary line, about two or more inches above the costal border, one is certainly dealing with a perforation of a gastric or duodenal ulcer."¹⁰⁷

FIG. 80. Abdominal and thoracic types of breathing.

A. Abdominal inspiration: As the diaphragm descends there is a downward force which tends to cause bulging of the lower abdominal walls (general increase in intra-abdominal pressure).

B. Thoracic inspiration: As the anteroposterior and transverse diameters of the thorax are enlarged there is enlargement also of the upper abdomen resulting in an upward pull or "lifting" force within the abdominal cavity and the lower abdominal walls tend to move inward (general decrease in intra-abdominal pressure). Note: The slight movement of the diaphragm has not been shown.

Pressure Variations with Various Types of Breathing

somewhat with the patient's type of breathing. With distinctly thoracic breathing (the costal muscles predominating) the general intra-abdominal pressure tends to fall during inspiration; with quiet normal breathing (combined abdominal and thoracic type) a fall in pressure within the upper abdomen synchronous with inspiration, is still observed; and it is only with the breathing of the abdominal type (thoracic cage remaining relatively quiescent) that the general intra-abdominal pressure shows any tendency to rise (increase) during the inspiratory act. The accuracy of these statements may roughly be tested by placing one hand over the lower portion of the abdominal wall and the other upon the upper portion while experiments are conducted with the various types of breathing, noting how the hands rise, sink or remain stationary during the inspiratory phase of the respiratory cycle.

Opening the Peritoneal Cavity

The presence of an upper abdominal negativity and one which tends to increase during inspiration, explains why there is a minimum of danger of injury to abdominal structures when the peritoneal cavity is opened at its upper levels, particularly when this is done during the act of inspiration. The daring surgeon will, at times, cut through the abdominal wall without taking the precaution of picking up the peritoneal membrane before incising it. He knows from experience that with the first nick of the peritoneum, air usually rushes into the peritoneal cavity and "the organs fall away from the abdominal wall as the potential cavity becomes real." This is not, as is so often stated, an index that the peritoneal cavity possesses at all times and in all situations a generalized sub-atmospheric pressure, but is due to the fact that during inspiration (particularly with the forceful type observed under general narcosis) the thoracic cage is enlarged and with it the circumference of the upper portion of the abdomen, i. e., the abdominal walls are moving *away from* the intra-abdominal viscera (Fig. 81). This maneuver of incising the peritoneal cavity without picking up the peritoneal membrane has been repeatedly executed with impunity, but the wisdom of the procedure

is open to question, since upper abdominal adhesions or intra-visceral distentions may have altered the pressure conditions which normally made the procedure possible. In opening the

FIG. 81.

abdomen at lower levels, where the effects of the thoracic respiratory expansions are less noticeable and there is no respiratory increase in the abdominal circumference, one should always pick up the peritoneum and lift it away from the organs below before it is incised.¹⁰⁹

4. THE EFFECT OF INTRALUMINARY PRESSURES. Each of the hollow viscera (stomach, intestine, gall bladder, urinary

bladder) has an intraluminary pressure of its own. These internal pressures are continually changing and they all have an influence upon the general intra-abdominal pressure. Any pressure change, whether an increase or decrease, within one organ must be compensated for by changes in other structures or by a change in the size of the cavity as a whole. The detailed study of these individual intrinsic pressures will be found elsewhere (see movements of the intestinal tract, basis of abdominal symptoms); but a few clinical points will be presented to illustrate the relationship existing between intravisceral, intraperitoneal and general intra-abdominal pressures.

Normal Disposal
of Intestinal
Gases

The most common cause of a general increase in intra-abdominal pressure from visceral distention is that which occurs with accumulations of gas or fluid within the gastrointestinal tract (tympanities; tumid abdomen; paralytic ileus). It is obvious that with a complete mechanical obstruction of the bowel there must result an increasing accumulation of contents (food, water, products of glandular secretion) cephalad to the point of obstruction. It is, however, not quite so obvious how an even more rapid collection of gas or fluid may occur within a loop of bowel which is isolated, i.e., one which has been cut off from the remainder of the enteric tract and is receiving no increase in substance from above, (example, strangulation ileus). This phenomenon, and others which must be dealt with in the diagnosis and treatment of the many varieties of intestinal obstruction, are due to the fact that the integrity of the circulation has more bearing upon the rate and severity of distention of bowel than has the integrity of the intestinal lumen.¹⁰⁹ Only a small proportion of intestinal gases are eliminated through the anus while the great bulk is absorbed into the circulation, there to be altered chemically or eliminated through other channels. The elimination of intestinal gases through the lungs alone is estimated to exceed that occurring by way of the anus by a proportion of ten to one. This explains the fulminating character of the

distention observed with mesenteric thrombosis. Indeed it is a general rule that the more sudden the occurrence of meteorisms the more likely is the cause to be an interference with blood supply rather than one of mechanical interference with the enteral lumen alone.¹¹⁰ The disappointing results which often follow the relief of a mechanical obstruction are probably due, in many cases, to vascular alterations which have concomitantly occurred. Thus it is usually necessary to empty the bowel at the time of operation for intestinal obstruction as well as to resect gangrenous gut or to remove the actual obstruction at the lumen. The statement has been made that no operation for intestinal obstruction may be considered complete if the abdomen remains distended at the time of abdominal closure.

Mesenteric
Thrombosis vs.
Mechanical Ileus

Much harm may result from suddenly decompressing an abdomen distended by paralyzed bowel, *in the presence of an acute peritonitis*. This is particularly true when the patient has reached a critical or moribund condition. To perform an ileostomy and allow the trapped gas and fluids to gush forth, as is sometimes done, until the ultimately desirable relaxation of the walls has occurred, must exert a great strain upon the circulation and have an effect upon protective adhesions somewhat similar to that of running the hands through the abdomen, pulling one loop of bowel from another until all pockets of pus have been turned into a single pool. Patients so handled not infrequently die a few hours after operation with evidences of circulatory failure and with a steadily rising temperature. After the ileostomy has been performed, the catheter or tube leading from the bowel may, to advantage, be intermittently clamped and opened, and the pressure thus more carefully and gradually reduced.

Ileostomy with
Peritonitis

It has been suggested that splanchnic nerve block or spinal anesthesia be utilized in selected cases as a therapeutic measure for securing relief from intestinal stasis.¹¹¹ The process is described as an activation of the vagus, or motor mechanism of the bowel, secured through an induced paralysis

Splanchnic Nerve
Block for Paralytic
Ileus

of the splanchnic nerves, which have been exerting an undue inhibitory influence upon enteral motility. (Fig. 82.) Care must be used in applying this suggestion since the method

FIG. 82.

A. Splanchnic analgesia. Position of patient. The point just under the twelfth rib marks the site of puncture, and the cross, vertically under, is the spinous process of the first lumbar vertebra. The distance between the two is 4 fingerbreadths or 7 cm. (From Labat's Regional Anesthesia, Saunders.)

is theoretically not suitable to cases with mechanical or spastic obstruction, but is of use only in the paralytic or adynamic cases.

Considerable intravisceral pressure may safely be endured within an organ which has walls of normal strength. But even a much diminished pressure may later cause a rupture of this organ when its walls have become necrotic or have been injured. Thus a distended gall bladder, undergoing a reduction

The Rupture of a
Viscus

in size under expectant treatment while the patient is apparently progressing satisfactorily toward a cure, may suddenly perforate and post-mortem examination reveal that the wall

FIG. 82.

B. Cross-section through the first lumbar vertebra, showing the method of inducing splanchnic analgesia. The needle has been inserted on the lower border of the twelfth rib, 7 cm. distant from the midline of the back. The dotted line marks the direction of the needle introduced toward the spine at an angle of 45 degrees with the median plane of the body. Note its point of contact with the vertebra; the needle is here in its last and good direction: tangent to the body of the vertebra. (From Labat's Regional Anesthesia, Saunders.)

had gradually become weakened from an impacted stone or from an area of gangrene caused by infection and thrombosis. Again, it is well known that the site of an intestinal anastomosis is stronger shortly after operation than it is from three to five days later when sutures have softened and liquefaction necrosis has occurred in traumatized areas. At the time of such secondary weakness the injured area should be carefully protected from excessively high intraluminary pressures. It is preferable to gently introduce a stomach tube promptly

upon the onset of vomiting in the early postoperative period after gastroenterostomy than to allow an overfilling of weakened walls at a later period.¹¹² Lavage may be intermittent or continuous (see Kanavel, Bossler and Levin tubes).

Exploring the
Abdomen

At the time of operation the abdomen is often found to be filled with distended intestinal loops making it difficult to conduct a proper exploration. There seems scarcely room to crowd the examining hand into the overfilled space. Lateral retraction of the wound margins only serves to favor evisceration. Strong *upward* retraction, however, draws the anterior abdominal wall away from the distended viscera and provides ample space through which to slide the examining hand to all parts of the peritoneal cavity without causing displacement of organs or needless trauma. Such traction away from the viscera also proves of aid when the peritoneal margins are being sought and when they must be grasped by forceps without causing injury to other structures.

Gastromesenteric
Ileus

An important example of an increased intraluminary pressure is the condition known as gastromesenteric (or duodenomesenteric) ileus.^{113,114} Here the stomach and proximal duodenum undergo rapid and tremendous dilatation; at times the greater curvature of the stomach may within a few hours reach to the level of the pelvis, the gastric distention causing considerable displacement of movable structures within the abdomen and thorax. The outstanding triad of symptoms of gastromesenteric ileus is; pain (which may become excruciating as the distention increases); repeated, effortless vomiting; and cyanosis. These are immediately and dramatically relieved by the passage of a stomach tube. They may, however, rapidly recur as the intravisceral tension again rises. Repeated lavage yields repeated relief. The condition is supposedly caused by a constriction of the terminal duodenum as it is crossed by the root of the mesentery of the jejunum, and particularly by compression of the duodenum against the vertebrae by the superior mesenteric artery. (Fig. 83.) Gastromesenteric ileus is a relatively frequent

complication of intra-peritoneal operations, particularly those performed within the pelvis. The condition is predisposed to by anything which causes downward traction upon the

small intestines and puts tension upon the mesentery. A change in posture of the post-operative suffered, placing him face downward, tends to relieve the duodenal compression and is the surest measure for producing permanent relief. The condition, often unrecognized, is an urgent complication having a high mortality but one which, if treated early, may quite certainly and promptly be cured through a combination of postural treatment and gastric lavage.

Eponym

FRIEDRICH TRENDELENBURG

- Eponym:** Trendelenburg position.
- Nativity:** Berlin.
- Birth-Death:** May 24, 1844. December 15, 1924.
- Education:** Earliest education was received at home (was taught English by his mother, Latin and arithmetic by his father, grammar by his aunt).
Subsequently attended a boys' school in Berlin.
In 1862 was give the option of attending a boarding school in Berlin or going to Scotland with his family for the year; chose the latter.
1863. Went from Edinburgh to Glasgow, where he studied anatomy, embryology and physics; tutored in family with whom he lived.
1863. Matriculated in University of Berlin.
1864. Took preliminary medical examinations. Studied surgery and internal medicine in clinics of von Langenbeck, Traube and Jungen.
1865. Travel study in Jena, Halle, Heidelberg and throughout central Germany.
1866. Received degree in medicine. Made military surgeon in hospital in Gorlitz.
1867. Took state examinations and wrote his thesis on Ancient Indian Surgery (De veterin Indorum chirurgia). Military surgeon at Kiel.
- Connections:** 1868-74. Assistant to Langenbeck.
1872. Founded German Society of Surgeons.
1874-75. Director of surgical ward, Friedrichschain Hospital, Berlin.
1875-82. Ordinarius of surgery, University of Rostock.
1882-95. Ordinarius of surgery, University of Bonn.
1895-1911. Ordinarius of surgery, University of Leipzig.
1898. Chairman, German Society of Surgeons.
1923. Historian, German Society of Surgeons.
- Writings:** Trendelenburg did important work with regard to plastic surgery, congenital hip joint disease, physiology of varicose veins, pulmonary embolism, gynecological and abdominal surgery.
Among his papers were the following:
Ueber Heitung der Harnblasen Ectopic durch directe Vereinigung der Spaltrander (1886).
Ueber Isobering in Chirurgischen Kliniken (1892).
Ueber Operationen zur Heilung der Angeborenen Harnblasen und Harnrohrenspalte (1892).
Zur Operation der Blasenscheiden Fisteln von der Blase Ous (1892).
Chirurgische Krankheiten der Gesichtsnerven (1908).
- Source of Eponym:** Ueber Blasenscheidenfisteloperationen und ueber Beckenhochlagerung bei Operationen in der Bauchhohle. (*Volkmanns Samml. klini. Vortrage*, Leipzig, 1890.
- Discussion of Eponym:** The Trendelenburg position was first recorded by Willy Meyer in 1885. Meyer was then a student of Trendelenburg and published the description with the permission of his "venerable chief." (See photostat, Fig. 84.)
Trendelenburg himself first wrote concerning "high pelvic elevation" in 1890 (see photostat, Fig. 84).
The position was an attempt to introduce air into the open bladder following the "principle of Sims' posture (1845) where the vulva is the most elevated point of the body and the opened vagina admits the air because of negative intrapelvic pressure and thus becomes distended."

(Chirurgie No. 109)

Über Blasenscheidenfisteloperationen und über Becken-
hochlagerung bei Operationen in der Bauchhöhle.

Von

Friedrich Trendelenburg,

in Bonn

Mit einer Lichtdrucktafel.

Seit ihrer Begründung durch Naegele, Dieffenbach und Jo-
bert de Lamballe ist die Operation der Blasenscheidenfistel, besonders
durch das operative Talent und die unermüdliche Ausdauer von Gustav
Simon, zu einem so hohen Grad von Vollkommenheit gebracht worden
dass dieses Kapitel der gynäkologischen Chirurgie auf den ersten Blick
fast vollständig abgeschlossen zu sein scheint. Neuere Vorschläge be-
ziehen sich auf Modifikationen der Instrumente, der Lagerung und des
Nahtmaterials, der Vorbereitung zur Operation und der Nachbehandlung,
das Princip der Operation bleibt immer dasselbe.

Meine ersten, allerdings erfolglosen Versuche in dieser Richtung
(1881 u. 1884)¹⁾ sind ziemlich unbeachtet geblieben. Nur König hat
sich wiederholt²⁾ Es hängt dies damit zusammen, dass auch die »Becken-
hochlagerung«, welche allein das Innere der Blase so aufzuschnellen
vermag, dass man feinere Operationen in der Blase vornehmen kann,
längere Zeit nicht die Beachtung gefunden hat, die sie meiner Überseu-
gung nach verdient.

Ich möchte daher das Wesen und die Vortheile dieses Verfahrens
in kurzen Worten nochmals hervorheben.

Lagert man den Körper eines Kranken auf dem Operationstisch so,
dass die Symphysis pubis der höchste Punkt des Rumpfes ist und die
Axe des Rumpfes mit der Horizontalen einen Winkel von wenigstens
45° bildet, so sinken sämtliche Eingeweide, vor Allem Leber, Milz und
Mesenterium, durch ihre Schwere in die Höhlung des Zwerchfells hinun-
ter. Der Darm folgt und fällt aus dem kleinen Becken heraus, so weit der
Luftdruck dieses zulässt. Bei mageren Individuen und erschlafenen Rektum
in tiefer Narkose wird die vordere Bauchwand in der Regio hypogastrica
von der Beckenhöhle her förmlich angesaugt, so dass sich in dieser Ge-
gend eine tiefe Grube bildet.

Macht man nun in der Regio hypogastrica zum Zweck des Stein-
schnitts einen Längs- oder Querschnitt und spaltet die Rektum sowie die
hinter ihnen liegende Fascie, so tritt sofort Luft in den prävesicalen
Raum ein, oft mit hörbarem Geräusch, die Peritonealfalte fällt herunter,
und aus dem prävesicalen Spaltraum wird ein weitklaffender Hohlraum,
in dem das Licht frei hineinscheint und in dem das Auge die vordere
Wand der Blase und die Umschlagfalte des Peritoneum sehen kann.

FIG. 84A.

[221]

A. J. S., n. s. Vol. VIII, No. 5, p. 1153

Friedrich Trendelenburg,

Ebenso überraschend ist der Nutzen der Beckenhochlagerung bei intraperitonealen Operationen in der Beckenhöhle und den unteren Abschnitten des Bauches.

Es handelt sich z. B. um eine Darmresektion, durch welche ein widernatürlicher After am Schenkelring (nach Brucheneinklemmung) beseitigt werden soll. Die Patientin wird in Beckenhochlage gebracht, dicht oberhalb der Fistel (die Patientin stehend gedacht) wird ein etwa 10 cm langer bogenförmiger Schnitt parallel dem Poupart'schen Bande durch die Bauchdecken gemacht, das Peritoneum wird incidiert, Luft dringt in die Peritonealhöhle ein, sämtliche Darmschlingen rutschen nach dem Zwerchfell zu hinab. Die Wundränder werden mit Haken auseinander gezogen, und wir sehen nun in das leer gewordene kleine Becken hinein, wir übersehen die ganze Fossa iliaca, und der einzige Darmteil, der sich präsentiert, ist die an den Schenkelring angelobete Schlinge. Wir können das Verhalten ihrer beiden Schenkel zu einander mit dem Auge kontrollieren, können sie bequem mit dem Finger anhaften, hervorziehen, durchschneiden und vernähen, kein Inhalt fließt aus, da, was von flüssigem Inhalt etwa noch da war, nach dem Zwerchfell zu abgeflossen ist. Wir arbeiten dabei im vollen Licht des gegenüberliegenden Fensters, wie der Maler an seiner Staffelei, ohne genötigt zu sein, uns zu bücken und, falls die Narkose ruhig ist, ohne durch heraustretende Darmschlingen belästigt zu werden.

In gleicher Weise machen sich die Vortheile der Beckenhochlagerung bei allen gynäkologischen Operationen in der Beckenhöhle geltend und ich glaube, wer einmal einen Uterus mit Myomen oder eine vergrößerte Ovarialzyste in dieser Weise exstirpiert hat, wird sich nicht leicht dazu entschließen zu dem alten Verfahren zurückzukehren. Soweit ihre Verbindungen im kleinen Becken es gestatten, fällt die Geschwulst aus der Beckenhöhle heraus dem Operateur entgegen, alle zu trennenden Verbindungen spannen sich an, das Blut fließt von dem Operationsfeld ab, um die Dürre braucht man sich, so lange kein Blutbrechen erfolgt, garnicht zu kümmern, als bleiben bescheiden in der Magengrube liegen, vor Allem man sieht was man macht.

Dass der Druck in dem unteren Abschnitt der Bauchhöhle bei der Hochlagerung des Beckens ein negativer wird, lässt sich an einem Manometer leicht demonstrieren. Man braucht dasselbe nur durch einen Gummischlauch mit einem Katheter in Verbindung zu setzen, welcher in die Blase eingeführt ist. Bei horizontaler Lage des Körpers ergab sich bei einigen Versuchen ein Druck von $+1$ cm, bei Beckenhochlagerung ein Druck von -6 bis 8 bis -11 cm Wasser.

In historischer Beziehung ist zu bemerken, dass die Beckenhochlagerung schon von den alten Chirurgen bei der taxis eingeklemmter Brüche angewandt wurde, die eingeklemmte Darmschlinge sollte durch die Schwere des Mesenterium aus der Bruchpforte herausgezogen werden, durch kräftiges Schütteln des Körpers suchte man das Herausgleiten zu befördern. So empfiehlt Fabricius ab Aquapendente, den Kranken an Händen und Füßen aufzuhängen, den Kopf hintenüber und das Becken höher als den Thorax, und den Schwelenden tüchtig zu schütteln. Corvillard liess den Kranken an den Beinen aufliegen. Nach Sharp soll ein Gehilfe den Kranken auf den Rücken nehmen, die Unterschenkel über die Schultern ziehen, so dass die Kniekehlen des Kranken gerade auf den Schultern des Trägers ruhen. Auch dabei wurde geschüttelt. Ähnlich verfuhr Ribes', Freund' lagerte einen Patienten bei der Exstirpation des catenariformen Uterus (1818) auf einem Tisch.

Ich selbst habe die Beckenhochlagerung zunächst nur bei Operationen an der Blase zu dem Zweck angewandt, um nach der Einföhrung der Blase durch hohen Steinschnitt das Innere der Blase dem Tageslicht und dem Auge zugänglich zu machen (1850). Mit der Freund'schen Mittheilung hatte die Sache nichts zu thun, es schwebte mir vielmehr das Princip der Seitenauflage von Sims (1853) vor, bei der bekanntlich die Vula den höchsten Punkt des Klumpes bildet und die geöffnete Vagina in Folge des negativen Druckes im Becken Luft aspirirt und dadurch zum Hülfsen gebracht wird. In gleicher Weise wollte ich die geöffnete Blase auch mit Luft füllen lassen. Erst später wurden mir die grossen Vortheile der Lagerung für die Operation des hohen Steinschnittes selbst klar, und dieselbe auch bei Laparotomien anzuwenden war ein weiterer sehr natürlicher Schritt. Seit 1881 operire ich bei jedem hohen Steinschnitt, seit Winter 1887 bei allen Laparotomien, wo es sich um Operationen in der Beckenhöhle handelt, von Anfang an nur in Beckenhochlagerung, und es ist kein Semester vergangen, wo ich meinen Zuhörern nicht die eine oder andere Operation der Art demonstrieren hätte.

Über die Technik der Beckenhochlagerung ist nicht viel zu sagen. In den ersten Jahren liess ich einen am Kopfende des Operationstisches stehenden Wärter die Knie des Patienten rücklings auf die Schultern nehmen, wie es die Alten mit ihren Bruchkranken machten, seit längerer Zeit benutze ich einen von Fachbaum konstruirten besonderen Apparat, der an dem Kopfende des Operationstisches angebracht wird. Fachbaum hatte ihn auf der Kölner Naturforscherversammlung (1885) ausgestellt. — Man beginnt die Operation erst wenn die Narkose vollständig geworden ist und alles Pressen und forcirte Athmen aufgehört hat. Auch während der Operation ist darauf zu achten, dass die Narkose eine vollständige bleibt durch die tiefe Lage des Kopfes wird sie gewöhnlich in keiner Weise ungünstig beeinflusst. Je magerer das Individuum ist und je leerer der Darm, um so mehr kommen die Vortheile der Lagerung zur Geltung.

Ueber die Nachbehandlung des hohen Steinschnittes sowie über Verwendbarkeit desselben zur Operation von Blasenscheidenfisteln.

Von
Dr. Willy Meyer,
Assistenten an der chirurg. Universitätsklinik zu Bonn.
(Mit einem Holzschnitt)

Bei der grösseren Beachtung, welche der hohe Steinschnitt in den letzten Jahren wieder gefunden ist die Frage der Nachbehandlung vor allen eine häufig ventilirte. Primäre antiseptische Blasen- naht — mit oder ohne Einlegen eines Verweilkatheters — und Oclusivverband, und Drainage der Blase durch die Bauchwunde mit offener Wundbehandlung oder folgendem Lister'schen Ver- bände stehen sich noch gegenüber. Auch Offenlassen der Blasen- wunde ohne jede Drainage ist versucht worden

514

Dr. Willy Meyer,

stützen, die Patienten mit Blasen-tumor möglichst früh der Opera- tion zu unterziehen, noch ehe die Kranken durch die Blutungen zu sehr geschwächt sind und ehe sich Nierenerkrankungen einge- stellt haben

Es sei hier noch der bereits kurz berührten Lagerung des Kranken gedacht, die Herr Prof. Trendelenburg seit längerer Zeit bei Operationen im Inneren der Blase in Anwendung zieht. — Wie die beige-fügte Skizze des Herrn Dr. Stricker (s. die Figur) trefflich veranschaulicht, wird der Patient (nach eröffneter Blase) auf dem Operationstische vollkommen umgedreht. Der Kopf liegt tief unten, Hintertheil und Becken hoch erhoben auf dem Rande des Kopfstückes. Ein Wärter, welcher dem Operationstische den

Ueber die Nachbehandlung des hohen Steinschnittes u. s. w. 515

Rücken zuwendet, hält die gespreizten und in den Knien gebeugten Beine des Patienten auf seinen Schultern fest und sorgt so für unverrücktes Einhalten der Lage. Wie leicht begreiflich sinken jetzt die Eingeweide, der Schwere folgend, nach dem Zwerchfell zu herunter, die eröffnete Blase klappt — nach Art der Vagina bei der Sims'schen Seitenlage — und gestattet nicht nur vollkommen freien Einblick in das Innere, sondern auch, nach Auseinanderhalten der Bauch- und Blasenwandränder vermittelt breiter, stumpfer Wundhaken, am Besten wohl der grossen v. Langenbeck'schen Resectionshaken, oder nach Anziehen einer jedersits durch den Wundrand geführten Fadenschlinge, bequemste Einführung der zur Exstirpation und sonstigen Manipulationen notwendigen Instrumente. Besonders zugänglich für Instrumente und Blick wird auf diese Weise auch die Gegend des Trigonum laeutaudii, der häufigsten Insertionsstelle der Blasen-tumoren. Steht der Operationstisch, wie gewöhnlich, mit dem Fussende dem Fenster zugewandt, so fällt das Licht eben direct vom Fenster her in den unteren hinteren Abschnitt der Blase hinein und erhellt so nicht nur das Orific. int. ureth., sondern auch sehr ausgiebig die Gegend der Ureteren- mündung. Man kann so Beobachtungen machen, die bei der ge- wöhnlichen Rückenlage nicht möglich sind.

Fig. 84c.

[223]

Trendelenburg was also influenced in his belief that the movable viscera might be carried out of the pelvis by the aid of gravity by his knowledge of the method employed by Fabricius of Aquapendente and others in the treatment of incarcerated inguinal and femoral hernias (hanging patients by feet or by hands and feet while the suspended body was shaken or jostled).

The position as first employed was maintained by an assistant who stood with his back to the patient, the patient's legs being flexed over his shoulders (see Fig. 84). Special supports, attached to the operating table, were later perfected and it then became unnecessary to hold the patient in the desired posture manually.

It has been written that "to have thought of high pelvic elevation (when surgical gynecology was a science still in its infancy) so that all organs drop out of the operative field, was as much of a feat as when Columbus made the egg stand on end."

Points of Interest:

Trendelenburg's family dates back to 1459. His great-great-grandfather was a physician, his grandfather a lawyer, his father a professor of philosophy at the University of Berlin. Trendelenburg was the only living son in a family of eight children (six sisters and one brother who died in early youth).

He married in 1874 (Charlotte Fabricus) and was the father of six children. His family life was most happy and in later years he traveled extensively with his wife and children.

Trendelenburg's autobiography is modestly written and is a thoroughly charming document.

Special

TRANSLATION OF ARTICLE BY TRENDELENBURG

OPERATIONS FOR VESICOVAGINAL FISTULA AND HIGH PELVIC ELEVATION IN ABDOMINAL SURGERY

Since its establishment by Naegele, Dieffenbach and Jobert de Lambelle the operation for vesicovaginal fistula, particularly through the surgical genius and indefatigable energy of Gustav Simon, has been raised to such a high degree of perfection that one might well assume offhand the last word had been spoken on this subject in gynecological surgery. All later suggestions involved modification of the instruments and sutures used, posture, preoperative and postoperative treatments. Yet the fundamentals of the operation remained essentially constant.

My first and unsuccessful attempts with this method in 1881 and 1884 (*cf.* Meyer, W., *Arch. f. klin. Chir.*, 31: 521, 1885) remained practically unnoticed. König (*Verhdl. d. Deut. Ges. f. Chir.*, 17: 100, 1888) was the only one who tried it. One reason for this apparent neglect was that for a long time far less attention than it deserves was paid to "high pelvic elevation," which is the only method to make the interior of the bladder sufficiently accessible to permit undertaking more delicate operations inside the bladder.

Therefore I wish briefly to emphasize the character and advantages of this method.

If the patient is placed on the operating table so that the pubic symphysis is the highest point and the axis of the body forms with the horizontal an angle of at least 40 degrees, then all viscera, particularly liver, spleen and mesentery, drop by gravitation into the dome of the diaphragm. The intestines leave the small pelvis corresponding to the degree of the air pressure. In thin subjects under deep narcosis when the (abdomi-

nal) recti are slackened, the anterior abdominal wall in the hypogastric region becomes practically sucked into the pelvic cavity and forms a deep pit.

If at cystotomy the hypogastric region be longitudinally or transversely incised, separating the recti and posterior fascia, the air immediately and often audibly fills this prevesical space, the peritoneal fold drops down, the prevesical cleft opens into a wide cavity freely admitting the light and plainly exposing to view the anterior bladder wall and parietal-peritoneal fold. . . .

The advantage of high pelvic elevation is equally surprising in intraperitoneal operations of the pelvic and lower abdomen.

Take, for instance, a case of intestinal resection requiring the removal of an artificial anus at the femoral ring (after incarcerated hernia). The woman is placed in high pelvic elevation. Close above the fistula (patient imagined standing) a 10 cm. curved skin incision is made parallel to Poupart's ligament; the peritoneum is incised; the peritoneal cavity is filled with air; all intestinal loops slide down to the diaphragm. The edges of the wound are retracted with hooks. In the empty small pelvis before us we can survey the entire iliac fossa; the only presenting intestinal portion is the loop adhering to the femoral ring. We can optically control the behavior of its two legs; we can draw it forward with the finger, cut and suture it. It will not leak for whatever fluid it contained has been drained in the direction of the diaphragm. The surgeon operates in the full light of the window opposite, as the painter at the easel; he does not have to stoop, nor is he annoyed by protruding intestinal loops provided the patient is quiet during narcosis.

The advantages of high pelvic elevation become equally apparent in all gynecological operations of the pelvis. I believe no surgeon will revert to the former method who once tries hysterectomy for myoma, or extirpation of an adherent ovarian cyst in high pelvic elevation. The tumor from the pelvic cavity fairly drops into the surgeon's hands so far as adhesions in the small pelvis will let it; adhesions for separation are taut; the blood runs off the operating field; if the patient does not vomit then the intestines require no attention for they modestly retire to the pit of the stomach. Above all, the surgeon sees what he does! . . .

Manometric demonstrations readily show that in high pelvic elevation the pressure in the lower abdomen becomes negative. The manometer is connected by a rubber tube with the catheter introduced into the bladder. Tests made at horizontal posture showed plus 1 cm. pressure, at high pelvic elevation minus 6 to 8 to minus 11 cm. water pressure.

With respect to the history of high pelvic elevation we find that the method was already used by early surgeons in taxis of incarcerated hernia. The idea was to withdraw the incarcerated intestinal loop from the hernial aperture by the weight of the mesentery; by forcibly shaking the patient at the same time it was hoped to accelerate the procedure. Fabricius ab Aquapendente recommended suspending the patient by hands and feet, with the head dropped backwards and the pelvis raised higher than the thorax and in addition thorough shaking of the swinging patient. Corvillard suspended his patient by the legs. Sharp employed an attendant who supported the patient on his back in such a manner that the legs were drawn over the carrier's shoulders on which the popliteal spaces of the patient rested. The carrier also had to shake the patient. Ribas employed a similar method. Freund (*Volkmann's Sammlung klin.* No. 133) extirpated a carcinomatous uterus in 1878. . . .

Personally I first employed high pelvic elevation in bladder surgery (in 1880) for the purpose of exposing the interior of the bladder to daylight and optic inspection after opening the bladder by suprapubic cystotomy. My method is quite independent of Freund's report. I had in mind rather the principle of the Sim's posture (1845) where the vulva is the most elevated point of the body and the opened vagina admits the air

because of negative intrapelvic pressure and thus becomes distended. Similarly I intended to admit air into this opened bladder. Sometime later I realized the great advantage of the posture in suprapubic cystotomy and it was quite natural to employ it also in laparotomy. Since 1884 I have been using high pelvic elevation in every suprapubic cystotomy; since the winter of 1887-1888 I have used it in every laparotomy for intrapelvic surgery. Not a single term has passed without my demonstrating either of these operations by the above method. . . .

There is little to say on the technic of high pelvic elevation. In the beginning I stationed an attendant at the head of the operating table and suspended the patient's knees over his shoulders in much the same way the early surgeons used in hernial surgery. For some time I have now used a support especially designed by Eschbaumn and fixed to the head of the operating table. Eschbaumn exhibited it at the meeting of the *Naturforscher* at Cologne in 1888. The operation should be started only after narcosis is established and pressure or forced respiration has subsided. During operation deep narcosis should be maintained and it is usually not unfavorably affected by the low position of the head. The thinner the individual and the more empty the intestines the more obvious are the advantages of the posture.

TRANSLATION OF ARTICLE BY DR. WILLY MEYER REGARDING THE
TRENDLENBURG POSITION

AFTER-TREATMENT IN SUPRAPUBIC CYSTOTOMY AND ITS APPLICABILITY IN THE SURGERY OF VESICOVAGINAL FISTULA

We shall briefly describe the posture of the patient which Professor Trendelenburg has employed for some time in operations of the inner aspect of the bladder. The appended sketch by Dr. Sticker (see woodcut p. 514) demonstrates that the patient (after opening of the bladder) is completely turned about. The head lies very low, the buttocks and pelvis are raised high and rest on the edge of the supporting end piece. The legs of the patient are flexed at the knees and in this position are placed respectively over the shoulders of an attendant, who turns his back to the operating table, and firmly holds the patient's legs. In consequence the intestines follow the law of gravitation and drop down in the direction of the diaphragm, the incised bladder opens—similar to the behavior of the vagina in the Sims' position—and permits not only a perfect survey of the interior of the bladder but also, after retracting the edges of the abdominal and vesical wounds with broad blunt retractors—the large von Langenbeck resection hooks are probably most suitable—or after holding back the wound edges by a loop of thread respectively, permits the introduction of all instruments required for removal or any other surgical methods. This posture especially permits a good survey of the *trigonum lieutandi*, the spot where vesical tumors are most frequently found inserted. If the foot end of the operating table faces the window, as is usual, the daylight directly shines into the lower posterior section of the bladder, and brings plainly into view not only the internal opening of the urethra but also the area where the ureters open. Thus observations can be made that are impossible in the "usual dorsal position."

QUESTIONNAIRE

1. Define chylous peritonitis, chyliform peritonitis, hemoperitoneum, choleperitoneum.
2. What are the chief causes of hemoperitoneum; the clinical picture?
3. What is meant by the leucocytosis following hemorrhage; by the leucocytosis of subserous hemorrhage?

4. Describe the leucocytic reaction following bleeding beneath serous membranes; plot the typical leucocytic curve.
5. What are the signs and symptoms of bile peritonitis?
6. What are the common causes of leakage of bile into the peritoneal cavity?
7. How can chylous and chyliform ascites be differentiated?
8. What are the chief causes of chylous ascites? How may this diagnosis be established?
9. What are the clinical findings with acute perforation of a peptic ulcer?
10. What conditions predispose to an intraperitoneal extravasation of urine?
11. What is the relationship between fractures of the pelvis and injuries to the bladder?
12. Name some of the methods for making a diagnosis of intraperitoneal urinary extravasation.
13. Is the bladder a pelvic or an abdominal organ?
14. Classify the causes of ascites.
15. What is the origin of ascitic fluid?
16. What percentage of cases of ascites is due to cardiac disorders?
17. What are the most common intra-abdominal conditions causing ascites?
18. What clinical evidence points to cardiac disease as the cause of ascites; to renal disease?
19. Describe the clinical evidence of cirrhosis of the liver.
20. What are the forms of tuberculosis of the peritoneum?
21. What percentage of cases of tuberculous peritonitis shows accumulations of ascitic fluid?
22. Give the clinical evidence pointing to the diagnosis of ascites due to tuberculous peritonitis.
23. What is meant by the Virchow-Troisier gland?
24. What is the significance of an enlargement of the left supra-clavicular gland in association with ascites?
25. Describe the clinical picture in a typical case of malignant peritonitis.
26. How often is malignant peritonitis a primary condition?
27. What are the most common sites of primary malignant growths which give rise to a secondary malignant peritonitis?
28. Name the most important large veins found within the abdomen.
29. What is the significance of jaundice associated with ascites?
30. What is the most common cause of ascites in children, in adolescence?
31. When edema of the legs precedes ascites, what is the most common cause of the latter?
32. What is the most common cause of ascites when this is associated with edema of the face and upper extremities?
33. What is meant by the term "intra-abdominal pressure?" What is this pressure in terms of millimeters of mercury or centimeters of water?
34. What is the normal pressure within the abdomen? Is it atmospheric, below or above that of the atmosphere? Give proofs.
35. In what respects are the pressure conditions within the abdomen similar to those within the thorax? In what respects are they different?
36. What is the basic factor which makes possible a subatmospheric pressure within the pleural cavities? Are conditions similar in regard to the abdomen?
37. What is the derivation of the word chest and the word belly? What fundamental functional differences are implied in these derivations?
38. What precaution must be taken in applying a plaster-of-Paris jacket which covers the abdominal walls? Why?

39. What is a scaphoid abdomen?
40. What conditions cause a scaphoid abdomen? What force or forces explain the shape assumed by the abdomen in this condition?
41. What is meant by the S-shaped or Gourd-shaped abdomen? Give the most common causes of this condition.
42. By what mechanism is the general pressure within the abdomen stabilized?
43. What is the effect upon the general intra-abdominal pressure of a sudden contraction of all the muscular walls?
44. Name some of the uses of the cough reflex for diagnosis.
45. What mechanical factor sometimes leads to dyspnea in certain abdominal disorders?
46. What is a phantom tumor? What is aerophagia?
47. What is the Murphy test for acute diseases of the gall bladder? Explain the mechanism of this sign.
48. When may it be of aid to palpate the abdomen with the patient in the knee-elbow posture?
49. Discuss the technic of abdominal palpation.
50. What is meant by the enteroabdominal reflex?
51. Why does not the injection of a given amount of air or fluid into the abdominal cavity have the same effect upon intra-abdominal pressure as the injection of the same amount of the same substance into the enteral canal?
52. What is the effect upon systemic blood pressure of a rise in the general intra-abdominal pressure?
53. What are the effects upon the abdomen of the subatmospheric pressure normally present within the pleural cavity?
54. Why is the diaphragm dome-shaped?
55. Give some proof that the pleural cavities exert some upward pull upon the abdomen.
56. Explain the obliteration of liver dullness.
57. Why is shoulder pain so frequent an accompaniment of free fluid or gas within the peritoneal cavity?
58. What effects do the thoracic movements have upon the general pressure within the abdomen?
59. Explain how it is possible for the pressure within the upper part of the peritoneal cavity to be lowered during the act of inspiration.
60. What are the various types of breathing?
61. What effects do these types of breathing have upon pressure variations within the abdomen?
62. What is the effect upon the circumference of the upper abdomen of a forceful inspiration with the thoracic type of breathing?
63. In what part or parts of the abdomen is subatmospheric pressure a normal condition?
64. In what part or parts of the abdomen is a positive pressure a normal condition?
65. What conditions tend to increase the pressure negativity within the abdomen? What conditions tend to increase the intra-abdominal pressure?
66. At what phase of the respiratory cycle is it most safe to incise the upper abdominal cavity (open the peritoneum)?
67. What is meant by intraluminary pressures? Intravisceral pressures? Static pressures? Illustrate.
68. What effect has a change in intravisceral pressures upon intraperitoneal pressures?
69. By what routes are intestinal gases normally disposed of? Give the approximate percentage eliminated through each route.

70. What is the effect upon the intestinal tract of an obstruction to the intestinal lumen?
71. Name some reasons why interference with the blood supply to the bowel leads to distention of the bowel.
72. Explain why gas may accumulate within a strangulated loop of bowel.
73. Why is distention of a viscus more dangerous at one time than at another?
74. What is the effect of a sudden release of an elevated intra-abdominal pressure?
75. What precautions must be taken to prevent circulatory disturbances after the removal of a large ovarian cyst?
76. What dangers are there in suddenly emptying the bowel by means of ileostomy, when the bowel is markedly distended in the presence of an acute peritonitis?
77. What is the effect upon the bowel of blocking the splanchnic nerves by a local anesthetic agent?
78. What is a gastromesenteric ileus?
79. Give the outstanding triad of symptoms of gastromesenteric ileus?
80. What is the accepted treatment for acute gastromesenteric ileus?
81. Explain the reasons for washing the stomach and for changing the posture of the patient with mesenteric ileus.
82. After what operations is a gastromesenteric ileus most common? What is the mortality after prompt treatment; with no treatment?
83. What may be done to facilitate an exploration of the abdomen when the intestines are markedly distended with gas?

COMPLICATIONS OF SPINAL ANESTHESIA*

HARRY KOSTER, M.D., F.A.C.S., AND MORRIS WEINTROB, M.D.

BROOKLYN, NEW YORK

IN reviewing the literature on the complications of spinal anesthesia it was found that in most instances phenomena that are part and parcel of the *modus operandi* of the anesthesia, that are but temporary in nature and that despite their unpleasantness are in no way a menace to future health or life are included as definite complications. Inasmuch as these so-called complications, to wit, the fall in blood pressure that is so frequently unnecessarily alarming to the anesthetist or surgeon, the nausea, retching or even vomiting of the patient within a few minutes after the injection of the anesthetic, the pallor, at times associated with a cold, disconcerting clamminess of the skin, and the enfeebled pulse, often barely perceptible, inasmuch as these so-called complications are by far the most frequently mentioned, and since they form the basis of a great deal of the objection that has been raised against the routine employment of spinal anesthesia, it seemed appropriate to present a paper with the subject of complications as its main theme.

A rather comprehensive survey of the literature was undertaken. Over two years of research were devoted to the subject and articles dealing with intraspinal anesthesia since its very inception were studied. The English, French, German, Spanish and Italian journals were searched for material. Inasmuch as the bulk of medical

literature finds expression in one of the foregoing languages a rather conclusive symposium was available. In view of the low incidence of complications following the use of intraspinal anesthesia as reported in these journals it seems fair to state that the injection of an anesthetic substance into the subarachnoid space preliminary to surgical intervention has been given the test of time and quantity and has been found to be exceptionally low in either frequent or serious sequelae.

Articles dealing with the subject have been reported on the completion of a series of cases ranging from 100 to 20,000 intraspinal injections. Most frequent mention is made of headache. Less frequently, reference is made to symptoms that are classified as meningeal in origin, being the result of either a meningismus or, even more rarely, a true meningitis. Occasional reference is made to the appearance of neurological disorders as, for instance, paresthesias, myelitis, anal and vesical incontinence, paralysis of the external rectus muscle of the eye, and tropho-neurotic disorders ranging from decubitus ulcers to a well-marked paraplegia. Mental aberrations varying from a mild psychosis to pronounced insanity have been recorded as sequelae. Syncope, coma and respiratory failure have been noted. The increasing popularity of subarachnoid injection as a means of inducing surgical anesthesia has stimulated the reports of accidents

* From the Surgical Service of the Crown Heights Hospital, Brooklyn, New York. Submitted for publication, May 20, 1930.

that have occurred as a result of lumbar puncture in itself. Indeed, an appreciable percentage of the fatalities that have occurred immediately after the injection of the anesthetic has been attributed to what some authors have seen fit to designate as "lumbar puncture shock."

HEADACHE

The most troublesome complication of spinal anesthesia is the occurrence of headache. The majority of patients thus afflicted begin to complain as a rule within the first twenty-four hours after the operation. Usually, the headache is either occipital or parietal in location and is frequently associated with some degree of stiffness of the neck muscles. The intensity varies. In most instances the discomfort is so mild that the administration of either aspirin or pyramidon or the application of an ice cap suffices. Rarely is the suffering of such great intensity that the usual analgesics are of no avail. In both the mild and the severe grades the headache is worse when the head and shoulders are raised. Relief is usually obtained in the former type by maintaining the horizontal position.

Headache is not only the most troublesome complication of spinal anesthesia but it is also the most frequent. According to the reports that have appeared in the literature the average incidence ranges in the neighborhood of 20 per cent. As high as 40 per cent, however, has been encountered. Mahler¹ in an experience of 1000 intraspinal anesthetics mentions but 10 per cent of headaches and calls attention to as high a proportion after simple diagnostic lumbar puncture. In the main these headaches disappear within twenty-four to seventy-two hours. The severe, agonizing, persistent type that resists the ordinary analgesics is rare. Indeed, in our own series of over 6000 cases their incidence has been no greater than 600, in other words, 10 per cent.

Featherstone² sent inquiries to 100 consecutive patients to whom he had

administered spinal anesthesia with the aid of tropococaine. Not one complained of serious disability that in any manner could be charged against the method of anesthesia. Headache and dizziness were the most frequent sources of complaint. Of 70 replies, some degree of late headache was said to be present in 28 cases, that is to say 40 per cent. One man complained; the remainder were women. He adds:

Astonished by the high incidence of the trouble, I wrote to 20 patients who, under general anesthesia, had undergone operations of a similar nature to those suffering from late spinal headache. There were 16 replies, and in 11 of these the patients had a headache. Thus, of those who under general anesthesia had undergone operation for conditions likely to cause headache, 68 per cent did in fact develop late headache. I think I am justified in blaming the patient's complaint rather than the spinal anesthetic for this late headache. Giddiness did not occur in those patients who were otherwise robust.

In our clinic the administration of spinal anesthesia is not limited solely to so-called poor surgical risks. In fact, save for such short procedures as the incision and drainage of an abscess and the like, subarachnoid block is induced routinely. It has been interesting to observe with what irregularity so-called spinal headache occurs. Frequently, a series of 100 cases, operated upon for varied surgical conditions, comprising all age groups and both elective and urgent conditions, poor risks and doubtful risks, will include but 2 per cent of mild headaches lasting no more than two or three days and amenable to the usual analgesics. In such a series the absence of agonizing headache will be noticeably in evidence. Then, again, a second series may contain as high an incidence as 20 per cent of the mild headaches and may show perhaps 1 or 2 or even 5 per cent of the more severe grade necessitating methods of treatment other than those ordinarily required. We have encountered marked headache that has persisted for more than one week

and that has recurred after temporary relief so that the duration of the affliction may be said to have existed for several weeks in but 5 instances out of a total number of inductions that at the present writing is as high as 6000 cases.

As is to be expected much theorizing has been done in an effort to explain the cause of this type of headache. Among the several ideas advanced are the following:

1. Loss of cerebrospinal fluid through the puncture wound in the dura by seepage into the extradural soft tissues.

2. An increase in the volume of cerebrospinal fluid contained within the subarachnoid space.

The mechanism of occurrence in the first instance has been ascribed to the lack of elastic and contractile tissue in the fibrous dural membrane. It is believed that the puncture hole caused in the dura by the needle point does not close until a fibrin clot forms or normal healing takes place. Castro Silva³ states that it has been his lot to perform laminectomies eight or fifteen days after a lumbar puncture and to find the tracts of the puncture still gaping, closed simply by non-adherent, epidural fat.

Upon the withdrawal of the needle, the dura and the underlying pia-arachnoid are left in one of two possible relations. Either the openings in the two membranes are superimposed, if the pia is drawn back through the dural opening by the needle, allowing leakage to take place or else the movement of the soft membranes upon each other causes the openings in the respective membranes to be situated at different levels. The force of the cerebrospinal fluid is then thought to compress the pia arachnoid against the dura for an interval long enough to permit the pial opening to close by virtue of its inherent elasticity. If the latter mechanism takes place very little cerebrospinal fluid will escape.

As a result of the considerable seepage of spinal fluid during the first few hours

after the operation, there is a disturbance of the intracranial portion of the cerebrospinal fluid. It has been claimed that the latter factor, by removing the watery cushion, allows the brain to sag against the bony framework of the skull. This in turn, supposedly, irritates the dural fibers of the trifacial and the two occipital nerves. Pressure upon the basilar venous plexus diminishes the outflow of venous blood from the cranial cavity and brings about an increase of venous tension. Lowering the patient's head is thought to remove the brain from contact with aforementioned nerves and venous plexus and thus tend to lessen the severity of the headache. Relief is similarly obtained when the opening in the dura has closed, seepage of fluid has ceased, and the normal watery cushion of the brain has been restored.

This type which may be referred to as the seepage type of headache is ascribed ordinarily to the lumbar puncture itself. The second variety of headache, however, is thought to be the result of an increase in the quantity of cerebrospinal fluid. Usually, other symptoms and signs are associated as, for instance, stiffness of the neck, photophobia, and more rarely, paralysis of the external rectus muscle of the eye with or without a concomitant diplopia. This syndrome is described as the postanesthetic meningitis or meningismus. Whereas in the former variety, the spinal fluid pressure may be very low, there is usually found an increase in the pressure associated with an increase in the cells and globulin constituents of the cerebrospinal fluid in those patients with meningismus. Thus, either a state of meningeal irritation is present or else, rather infrequently, a true infectious meningitis. Such headaches do not respond to the lowering of the patient's head.

Unfortunately, the literature is considerably at variance as to the cause of headache after either diagnostic lumbar puncture or after the intraspinal injection of an anesthetic. Burrus⁴ like many others attributes the headache to leakage and con-

demns the larger caliber needles because more fluid can escape through the larger opening and healing is proportionately delayed. We ran a series of over 300 cases with a fine caliber needle and found no appreciable change in the incidence of headache. According to Evans⁵ this seepage type of headache is associated with a diminished pressure and he counsels against a further lumbar puncture "as it will make this type of headache worse." Valdone⁶ on the other hand, reporting an incidence of 30 per cent (tutocaine anesthesia), after stating that he considered the loss of cerebrospinal fluid as the cause of headache, employed secondary lumbar puncture in 8 cases that failed to respond to caffeine, aspirin or pyramidon and concludes that his contention seemed "to be proved by the fact that the pressure of the cerebrospinal fluid was lowered." An interesting statement is that of Pardee who, after hearing Neustaedter, Hola and Tolstoochow⁷ report that they could find no definite relationship between the calcium content of spinal fluid and postlumbar headache, stated that he saw no reason for ascribing headache to leakage since, in his experience, it has been possible to "take out as much as 80 c.c. from the spinal canal and still have no spinal puncture headache even though the patient may get up immediately afterward." After reading such a statement, one becomes rather perplexed upon studying the recommendations of Wells⁸ for the technic of inducing spinal anesthesia with what he refers to as anhydrous cocaine.

We quote verbatim from his report as follows:

From 15 to 25 c.c. more of spinal fluid are then withdrawn from the spinal canal into a glass syringe using gentle traction on the plunger. The amount withdrawn is determined by the patient's reaction, which consists of a progressive headache, generally occipital. In the early part of the series we allowed the headache to go on until the patient uttered an involuntary high-pitched cry, but this has been found to be unnecessary. We now deter-

mine the part where headache starts and then continue to withdraw fluid slowly, stopping when we judge that the headache has reached the maximum.

The entire quantity of cerebrospinal fluid contained in the syringe with the dissolved anhydrous cocaine is then quickly reintroduced into the subarachnoid space and "immediate and complete cessation of headache takes place."

It is interesting to note that headache was not frequently encountered by Delmas,⁹ one of the foremost French exponents of spinal anesthesia, despite his technic which makes a particular point of first abstracting from 20 to 40 c.c. of fluid, employing barbitage to dissolve the anesthetic substance and increase the diffusion in order to induce whole body anesthesia.

The question of the treatment of headache is discussed from both the prophylactic and curative standpoints.

PROPHYLAXIS

The following recommendations have been made:

1. Use a small caliber needle.
2. Do not allow the patient to move or elevate the head while being operated upon and for several hours after the injection of the anesthetic.
3. Administer sufficient fluids preoperatively. According to Martin-Arbuthnot¹⁰ the patients on the urological ward of the Los Angeles General hospital have their black coffee and all the water they wish to drink before going to the operating room. Those on the general surgical service have their routine surgical preparation and no fluids by mouth on the morning of the operation and it is among the latter group that dull, frontal headaches are encountered. They recommend, therefore, that there be no restriction in the amount of fluids before operation.
4. Avoid the reintroduction of the spinal puncture needle. Careful attention to the technic of lumbar puncture will minimize

dural trauma and thus lessen both the incidence of leakage and the occurrence of irritative phenomena.

5. Do not inject air into the subarachnoid space or puncture the venous plexuses that surround the anterior and lateral aspects of the spinal column. Featherstone² remarking that the French have blamed the injection of air, points out that headache occurs after simple lumbar puncture where it is difficult to imagine how air could enter the subarachnoid space. Nor can we ascribe much importance to the few bubbles of air which we frequently inject since from 60 to 80 c.c. and even more are routinely injected in ventriculography without either routine severe headaches or disastrous results. Bagley¹¹ has endeavored to blame the incidence of headache in intracranial injuries upon the presence of blood in the subarachnoid space. Believing that this might be a clue to the causation of headache, we have paid particular attention to those patients in whom a bloody tap was obtained. At no time did we hesitate to inject the dissolved anesthetic provided that spinal fluid was obtained after the venous plexus had first been punctured accidentally. Such patients did not show a greater incidence of headache.

CURATIVE

1. Administer the usual analgesics first: aspirin, caffeine, phenacetine, pyramidon. Codeine or even morphia may be indicated.

2. Advise the patient to maintain a horizontal position and apply an ice cap to the head.

3. Darken the room, especially if photophobia or diplopia be present.

4. Eliminate all forms of stimulation (including too many visitors that may be productive of unnecessary excitement).

5. Administer 1 c.c. of either surgical pituitrin or from $\frac{3}{8}$ to $\frac{3}{4}$ of a grain of ephedrine hydrochloride intramuscularly.

6. In the seepage type of headache administer about 100 c.c. of 0.5 per cent sodium chloride solution intravenously.

Relief will come within twenty to forty minutes (Evans). Also, force fluids, using a Murphy drip if necessary.

7. Frequent lumbar punctures are advised for the type of headache associated with an increased spinal fluid pressure and meningismus. This procedure is to be resorted to only after relief has not been obtained from diuretics, cathartics and hypertonic saline solution both orally and intravenously. According to Evans⁴ the intravenous administration of 10 per cent glucose solution in physiological salt solution will relieve this type of headache if nothing else will. As much as 1000 c.c. may be given and it may be repeated after six to eight hours.

Early in our experience, we adopted one of the procedures that had proved of value in the treatment of increased intracranial pressure. Retentive enemata of 6 oz. of 50 per cent magnesium sulphate solution were prescribed. Usually, 1, 2 or 3 rectal injections at intervals of four hours were sufficient to relieve the mild forms of headache that did not respond to the ordinary analgesics and that were not severe enough to warrant a secondary lumbar puncture.

Recently, since some of the patients found it difficult to retain the solution for a time sufficient to allow of any therapeutic value and in some instances a mild proctitis developed, we adopted the intramuscular injection of 2 c.c. of 50 per cent magnesium sulphate as supplied in ampule form for the Gwathmey technic in obstetrics. A fair measure of successful results ensued. We accidentally discovered the increased efficacy of the drug when administered intravenously. A patient had already received one retentive enema which she had not retained satisfactorily and which had failed to relieve her of intense headache, stiffness of the neck and marked photophobia. Within several seconds after an intravenous injection of magnesium sulphate, she experienced a sensation of extreme warmth, perspired freely and became quite dry

in the mouth. Two minutes later, she gratefully stated that all her symptoms had miraculously disappeared. Other similar experiences have since established this as a rather reliable agent in our therapeutic armamentarium. Now, when we receive a complaint of slight headache, the patient receives a coal-tar preparation, usually aspirin. Moderate headache is treated by magnesium sulphate intravenously. Severe headache unrelieved by magnesium sulphate is invariably cured by one or two spinal punctures. In one instance, peculiarly enough, a nurse upon whom a cholecystectomy and appendectomy had been performed, cure was not effected even by repeated spinal taps. The empirical use of $\frac{1}{2}$ grain each of anterior pituitary and thyroid gland extracts produced an almost immediate cure.

It seems quite evident that there is still considerable information to be secured regarding the mechanism of the production of headache. Apparently, in most instances the caliber of the needles, blood in the spinal fluid, the injection of air and seepage are explanations which do not hold water. It is evident that in a fair proportion of cases, increased intracranial pressure (however produced) is an important factor.

BACKACHE

Backache occurs in a small percentage of cases. It may be due either to trauma of the soft parts that are traversed by the needle, especially when several attempts to enter the subarachnoid space have been made, or else to a serous meningitis resulting from the wound in the dura and pia, the liberation of a small quantity of blood by accidental penetration of one of the venous plexuses, or the introduction of rust particles from the needle, or even from the presence of several bubbles of air. No matter what the cause may be, the backache is but short in duration and is frequently relieved by placing a pillow under the small of the back.

In our experience, the incidence is approximately 2 per cent. It has never proved very troublesome nor has it ever persisted longer than a week. This period coincides with the time required for the repair of the local tissue-injury. In no instance that we know of has local supuration resulted, the tissues always being able to complete the reparative process without necrosis. The backache resulting from the induction of anesthesia must not be confused with that following the dorsal recumbent position on an operating table not fitted to conform to the curve of the spinal column. The former quite accurately can be localized to the site of the puncture; whereas the latter is a more diffuse ache.

The only treatment necessary is a local wet dressing and control by coal-tar depressants, although the former has been resorted to in only one instance in our series.

ANAL AND VESICAL DISTURBANCES

Often reference is made to anal or vesical incontinence as a possible complication. Most authors, however, remark that they did not encounter such a state of affairs or else an occasional case appeared wherein reestablishment of the normal functions required but several days to a week. Orth¹² for instance, reports a case of fecal incontinence that cleared up spontaneously after five days and Izquierdo¹³ one that persisted for a week. In Bazy's patient¹⁵ the fecal incontinence was due to the fact that sensibility of the anus had been lost. The need of evacuation was experienced as a peculiar sensation in the region of the pubis. Even after the patient had moved his bowels, he still had a sensation of fullness in the rectum.

On the third day after a double inguinal herniotomy under 0.12 gm. of stovaine, a patient of Sourasky¹⁴ developed urinary incontinence, that is, retention with overflow. This was soon followed by occasional fecal incontinence. Fully a year elapsed before complete restoration of functions

appeared. In a second case, an appendicular abscess in a boy of nineteen, incontinence disappeared at the end of three weeks.

Salleras¹⁵ operated upon a boy of seventeen for acute appendicitis who shortly afterward developed a marked vesical retention. The bladder would distend so that it could retain 800 c.c. of urine without any discomfort to the patient. Incontinence resulted from the overflow. Fecal incontinence was also present as well as exaggerated knee jerks, hyperactive tendo Achilles reflexes, ankle clonus and a positive Babinski reaction. This state, however, lasted only three weeks. Salleras advanced the theory that the medullary centers of defecation and urination had suffered damage as a result of a local irritation of the meninges. The latter gave rise to a meningitis which caused a compression of the area either by the increased quantity of cerebrospinal fluid formed in response to the irritation or by the presence of hemorrhage into the subarachnoid space brought about by the trauma of the needle or else damage to the centers resulted from the onset of a sclerosis.

A most interesting case has been presented by Vialard and Darleguy.¹⁶

A few days after an appendectomy under syncaïne intraspinal anesthesia, from 19 to 23 liters of clear urine were passed daily. Kidney function tests were normal. Physical examination was negative except for a sickly habitus. There was a negative urine save for a specific gravity of 1.001 to 1.002. The spinal fluid and Wassermann examinations proved normal. Several levels of hyperesthesia existed to wit, the trigeminal, C 7 to D 1, D 4, D 5, D 8, D 12, and L 1. Deep sensibility was normal.

Signs of adiposis dystrophia genitalia were not evident. The patient acknowledged, however, that he had suffered for some time from a slight trembling which was especially marked in the upper extremities. Following the onset of the polyuria, the patient lost considerable weight. When not eating or drinking because of anorexia, the trembling was exaggerated. It consisted of small, irregular, myoclonic

movements. Fibrillary twitchings were absent. The hands were cyanotic.

Roentgen examination of the sella turcica revealed apparently normal findings. And, also, a psychological examination was negative. The initial thirst became imperative and, when unable to satisfy this thirst, despite the fact that nothing was discernible, he complained of a sensation of swelling of the tongue and lips with itching and even painful smarting.

Urinary elimination did not accurately correspond with the intake, although retention of fluid in the tissues did not take place. The rate of elimination was influenced to some degree by position. Thirst was greater at night and the nightly output was from two-thirds to three-fourths greater than the daily excretion. On days when he was unable to leave his bed, however, the daily output was equal to the nocturnal. He complained of intermittent frontal and occipital headaches that were less intense while he was lying in bed. General feebleness and increasing anorexia appeared. Finally, he presented a typical attack of Jacksonian epilepsy with aura in the calf of the right leg.

Upon discharge from the hospital, his urine output was 20 to 23 liters a day and his weight was one-half that on admission.

On examining the family history, it was discovered that there had been a brother who had died as a result of meningitis at the age of three months. The patient himself had suffered from convulsions at the age of three months and some few weeks previous to admission had had a so-called nervous breakdown. Presumably, according to these authors, both had had during infancy a meningitis that caused the death of one and left latent sequelae in the other. The latter might well have been responsible for the nervous manifestations and for the seizure of Jacksonian epilepsy. Furthermore, there quite likely existed a meningeal plaque at the base of the brain.

According to the same authors, the work of Lhermite, de J. Camus, and Roussy as well as that of de J. Camus, Gournay and Legrand has demonstrated clearly that there exist groups of fibers in the tuber cinereum, the one regulating the metabolism of carbohydrates, the other the retention of water in the organism. The nucleus proprius of the tuber cinereum (situated superficially) would be the center of nerv-

ous polyuria. It is easy to conceive of the causation of the infundibulo-tuberien syndrome (nervous polyuria) resulting from a meningeal lesion limited to the base of the brain near the posterior aspect of the tuber cinereum. The lumbar puncture may have reactivated the latent meningitis either through the direct action of the injected anesthetic or more likely by simply disturbing the equilibrium of the dynamics of the cerebrospinal fluid. The intraspinal injection of sterile water or even of normal saline solution is followed by after disturbances as shown by the experiments of Guinard and Koslowski, later confirmed by Stolz and Schwartz.¹⁷

Bazy¹⁸ reported a case of herniotomy in a man of fifty-nine who for eighteen months after the operation experienced no desire to urinate. When the desire had finally returned, spontaneous contraction of the bladder failed to appear. Catheterization was necessary for the entire eighteen months. After progressive education of the abdominal muscles, catheterization was at last suspended at the end of two years. Still his difficulties were not at an end since, despite his ability to urinate normally at the beginning of his apparent restoration, he was later obliged to assume a crouching posture. Involuntary urination would take place if he neglected to void for from six to eight hours.

The necessity of catheterizing patients postoperatively occurs in 10 per cent of our cases. Of this number 90 per cent need only one or two catheterizations and the remainder void spontaneously after the third day.

In no instance did retention last longer than the stay in the hospital necessary for wound healing. Never did it last longer than ten days, expecting in the instance of a case at present still in the hospital. The patient, a male, forty-seven years old, was operated three weeks ago for carcinoma of the rectum. A bilateral inguinal gland excision and a transsacral extirpation of the rectum were performed. The patient has not as yet voided spontaneously. The urine

is clear. The bladder becomes distended so that the patient becomes uncomfortable and requests relief. At the operation there was no evidence of injury to the urethra or bladder wall. This urinary retention is the only complication presented by the patient.

We have given some thought to the possibility of a postoperative traumatic prostatic enlargement as the possible etiological factor and expect to receive more information by cystoscopic examination.

It is our impression that postoperative urinary retention is much more frequently encountered after inhalation narcosis.

Of all the cases presenting this complication, 75 per cent occurred after operations involving the perineum or pelvis or both. We rarely encounter vesical disturbances in head, neck or thorax operations.

It would seem therefore, that invasion of the pelvis either directly or indirectly through the medium of the upper portion of the peritoneal cavity to a lesser degree, predisposes to retention. Of course, perineal operative trauma is readily recognized as a responsible factor.

The hypothesis that the anesthesia induction produces a localized serous meningitis and thus disturbs the anal and vesical spinal centers in the lumbar region of the cord is contradicted by the statistical evidence demonstrating the greater frequency of retention following inhalation anesthesia.

In discussing vesical complications it might also be mentioned at this time that, frequently, following the anesthesia induction in a patient just catheterized, upon opening the abdomen the bladder may be found full. It was formerly assumed that the catheterization had been incomplete; but recent observations on kidney secretion following splanchnic section have presented a satisfactory explanation. It is found that splanchnic section or block results in the simultaneous activity of all the kidney glomeruli. Normally, part of the glomeruli rest while others function. With all of them active during any given time, urinary secretion is tremendously increased. Apparently,

glomerular activity is continuously controlled by impulses coming through the splanchnics. Spinal anesthesia which is high enough to block all the splanchnic influences (i.e., roots of the fifth to the twelfth dorsal and first and second lumbar nerves) abolishes this control and increased secretion results.

Treatment of this complication is limited. Catheterization is essential. Stimulation of the lumbar cord by the administration of strychnine and caffeine seems of little value. The influence of pituitrin on the bladder musculature is unreliable. The instillation of glycerine into the bladder has never been of value in our series. We have had no experience with electrical stimulation of the lumbar cord. We have found enemata second only to catheterization as a means of emptying the bladder. Nor do we hesitate to order them the first day after operation excepting in cases of colonic or intestinal resections or anastomoses.

We have had one experience with vesical incontinence directly referable to the anesthesia. This occurred in a female patient operated on for uterine fibroids. For the first eight days, she voided spontaneously. On the ninth day, it was reported that she was incontinent. Examination revealed a distended bladder reaching almost to the umbilicus. Fifty-two ounces of urine were obtained on catheterization. Following this, spontaneous urination reappeared.

No case of fecal incontinence has come to our notice.

OCULAR COMPLICATIONS

The literature contains but few references to the occurrence of ocular complications after intraspinal anesthesia. These are practically limited to paralysis of the extraocular muscles, usually to the external rectus which is supplied by the abducens or sixth nerve. Although ocular disturbances have set in from several days after the injection to as late as the second week after operation, cases have been reported wherein they occurred immedi-

ately following the lumbar puncture. As a rule, the complication, although unpleasant, proves to be transitory. After a maximum effect lasting from one week to ten days, the condition shows signs of beginning cure. Occasionally, complete cure does not take place until two months have elapsed.

Abducens paralysis is usually ushered in by a preliminary photophobia. Diplopia supervenes and is homonymous. Outward motion is limited and there is convergent squint. All these symptoms are exaggerated as the patient attempts to abduct the affected eye. Reber¹⁹ reported 5 cases of transient abducens palsy from the service of Babcock. These appeared after the use of ampules of stovaine and tropococaine that had been imported from Europe. The paralysis became evident seven days after operation. Both Reber and Babcock believed that infection followed the employment of contaminated solutions since no similar complication was encountered during the next eighteen years, during which period over 20,000 spinal anesthetics were administered. Valdoni²⁰ adds 3 cases in 500 inductions with 2 per cent tutocaine. Gagey²¹ reports 1 instance in 700; while Warnecke²² lists 8 in a series of 1800. Gagey's patient suffered from diplopia for two months; whereas the condition subsided completely in Warnecke's patients after the lapse of several days. Two cases were reported by Tits,²³ one four days and the other six days after the injection of 15 cg. of allocaine. Both, however, proved to be transient. Van Duyse fils²⁴ referred to 4 further cases similar to those of Tits. In one of his patients the paralysis of the abducens appeared shortly after the intraspinal injection but disappeared entirely at the expiration of several days. In another, however, ten days passed before any indication of ocular disturbance became evident nor did the patient begin to show the slightest sign of improvement until two months later. Satanowsky²⁵ adds one transient case of abducens palsy.

A functional optic neuritis occasionally accompanies abducens palsy. There is a

disturbance of vision, sometimes insignificant, at other times, rather marked. The degree of disturbance is not always proportionate to the degree of changes seen on ophthalmological examination. There may even be complete blindness, though temporary, as reported by Wells.²⁶ This alarming complication occurred in one instance out of a total of 557 cases by Wells after the use of anhydrous cocaine. Fortunately, the patient recovered completely at the end of five days of grave concern. Functional optic neuritis appeared in one of Tits' patients but vanished after several days.

Reboj²⁷ states that he has never encountered any case of choked disc as reported occasionally in the literature of spinal anesthesia. According to his views the infrequent paralysis of the trifacial, common oculomotor and external oculomotor nerves, and pressure on the optic nerve (choked disc) can be explained by hypertension of the cerebrospinal fluid consequent to a serous, toxic meningitis caused by the injected anesthetic agent. He recommends that decompressive lumbar punctures be instituted as soon as these signs appear.

Drooping of the left upper eyelid (the result of a paralysis of the branch of the oculomotor nerve which supplies the levator palpebrae superioris) was reported by Wells.²⁶ This disappeared at the end of two weeks and was encountered in but 1 case. Martin and Arbuthnot²⁸ in a review of over 6000 cases operated on under spinal anesthesia at the Los Angeles General Hospital mention but 1 ocular complication, an inability to move the eyeballs without causing intense pain. This was accompanied by numbness of the feet which persisted for two days, severe headache and neck pain that lasted for three days.

When paralysis of the external rectus occurs, it is usually unilateral, and as frequent in the right as in the left eye. It does however, occur bilaterally as reported by Lang,²⁹ Baisch,³⁰ Goettermann³¹ and Landow.³²

The majority of authors who have reported ocular complications after intraspinal anesthesia point out that one must not be too prone to consider the anesthetic at fault since similar disturbances occur at times following lumbar puncture alone. Guillain and Alajouanine and La Grange³³ have observed papillary hyperemia in patients who displayed other signs and symptoms of lumbar puncture intolerance, such as, headache, nausea and vomiting. Examinations previously showed normal eyegrounds. The papillary picture was remarkably constant and persisted several days after the subsidence of the other symptoms. In patients who complained of headache, vertigo and nausea of only several days' duration the ophthalmological picture showed only a congestion of the papilla without all the signs of a true papillitis. When no evidence of lumbar puncture intolerance was obtained, no ophthalmological changes occurred. Guillain and Alajouanine and La Grange believe that the papillary changes are caused by an intracranial, paroxysmal hypertension. This can be explained by a hypersecretion of the choroid plexus caused by the removal of cerebrospinal fluid or other modifications in the hydraulics of the fluid. This hypertension may impose an obstacle to the return circulation or it may produce symptoms of localized arterial hypertension.

Thus, the ocular complications of spinal anesthesia must be separated from those incident to the lumbar puncture. We have had the average experience, namely, 1 case of diplopia in 500 inductions, and all cleared up within two weeks.

The explanation usually given of the mechanism by which the sixth nerve becomes involved postulates an edema of the brain consequent to the injection. The long course of the sixth nerve at the base of the brain allows for relatively more stretching. This, it is believed interferes with its function. As the edema subsides, there is a recession of symptoms. If this explanation be valid, why does the diplopia frequently occur four, five or six days

after the injection? Why are there frequently no other symptoms of cerebral edema?

Another explanation advanced is that the sixth nerve is particularly susceptible to the effects of the anesthetic. While there is some evidence that different nerves are variously affected by anesthetics, why, again, the delayed activity? And why not a more uniform occurrence of this complication?

In the treatment of this condition, the element of time is the most important factor. Patients may be confidently assured of complete cure. Rest in the recumbent position is helpful.

Another complication is pain in the eyeballs on ocular movement. This is also best controlled by eye rest and depressants.

We have had a few cases of photophobia. These were associated with meningismus, and lasted no more than one week.

MENINGISMUS

The incidence of meningismus encountered by us is 1 in 600. It is usually ushered in on the day following the anesthesia induction with headache. Dizziness, stiffness of the neck, occasional inequality and sluggishness of the pupils, photophobia and eyeball pain follow. The symptoms are aggravated by raising the head and movement of the body.

The cerebrospinal fluid shows the picture of an aseptic meningitis. The symptoms last for two or three days and then subside spontaneously.

These patients are not relieved by coal-tar derivatives nor even by codeine. Magnesium sulphate by enemata or intravenously and spinal puncture are the only effective measures. They are used here as advocated above in the treatment of headache, the underlying principles being identical.

MENINGITIS

The occurrence of a true, purulent meningitis as a complication of intraspinal anesthesia is a rarity. Despite the warning

of certain authors that subarachnoid block is contraindicated in sepsis, numerous cases are on record wherein purulent meningitis did not result. Indeed, but 9 cases in all the hundreds of thousands of inductions over a period of over twenty years have been reported in the literature. Of these, only two resulted fatally. However, the data contained in the reports were so meager that it is possible that not all the cases cited had a true purulent meningitis.

During the first twenty-four to forty-eight hours after operation, the symptoms of headache, stiff neck, restlessness, ocular aberrations and increased temperature make their appearance. Shortly afterward the characteristic symptoms and signs of a purulent meningitis are in evidence. The spinal fluid is turbid, the globulin and cell findings are raised, and there is a variable degree of elevation in the pressure of the cerebrospinal fluid which contains organisms.

Cases of true purulent meningitis have been reported by Wertheimer,³⁴ Senge,³⁵ and Sanchis-Banus.³⁶ Boros³⁷ reported a case which he described as a case of cystic, purulent meningitis following lumbar anesthesia induced with novocaine. It was his only case in a series of 1439 induction over a period of eighteen years, during which he encountered 25 per cent of headaches. His patient was a twenty-five-year old man, operated upon for a right, incarcerated inguinal hernia. Twelve hours after operation, the patient complained of severe headache, became restless and lost consciousness. At the end of three hours all the cardinal symptoms of meningitis were noted. Boros administered 40 per cent urotropine solution intravenously. Upon lumbar puncture a sterile, turbid fluid under high pressure was obtained. He repeated his injection of urotropine and gave in addition 10 c.c. of trypaflavine intravenously. The symptoms gradually regressed and by the sixth day had ceased entirely. The novocaine was examined and found to be sterile. Boros quotes a similar case in the experience of Pautrier. Silva³ adds 2 fatalities, occurring a few minutes

after the intraspinal injection, the spinal fluid being very turbid in one.

Meningitis has occurred after diagnostic lumbar puncture alone. Symonds³⁸ reported a case that recovered after the institution of irrigation of the subarachnoid space. Sonnenschein,³⁹ however, presented a case of meningitis following diagnostic lumbar puncture that terminated fatally.

It would seem, therefore, that meningitis following intraspinal anesthesia need not necessarily result from the use of contaminated anesthetic agents, or ensue in a patient suffering from septicemia consequent to the establishment in the meninges of a *locus minoris resistentiae* brought about by the trauma of the lumbar puncture needle.

We have operated upon at least 30 patients in whom there were positive blood cultures without the production of a meningitis. It is our belief that such cases do not offer a contraindication to the use of spinal anesthesia.

Five years ago, seven days after an appendectomy in a sixteen-year old girl, classical symptoms of meningitis developed. Examination of the cerebrospinal fluid revealed the meningococcus as the causative agent. The biological characteristics of this organism ruled out the likelihood of any but a coincidental relationship of the meningitis to the anesthesia. This case terminated fatally after three weeks.

In a recent unpublished report of 496 spinal anesthetics from a local institution there was 1 fatal case of meningitis due to a pyocyanus infection.

It must be remembered that suppuration at the puncture site is a definite contraindication to spinal anesthesia. Van Lier¹⁰ reported a staphylococcus meningitis as a result of passing a needle into the subarachnoid space after traversing an unsuspected abscess in the sacrospinalis muscle. The cerebrospinal fluid was but slightly contaminated and the patient recovered.

The treatment of this complication needs no discussion here.

INJURIES TO NERVES

Nerve injuries following spinal anesthesia are fortunately rare. Furthermore, they are usually transient in nature. Exceptionally, symptoms and signs may exist for many months and cause not only great discomfort and annoyance to the patient but also considerable chagrin to the surgeon.

Damage to the spinal cord or to the roots may result in anesthesia, paresthesias, trophoneurotic changes leading to atrophy of muscle groups, decubitus ulcers, sharp, lancinating pains along the course of nerves, and transient anal or vesical incontinence. If more severe damage has taken place, transient paresis may be replaced by permanent paralysis, although the latter is even more rare than the sequelae of the milder forms of nerve irritation or trauma. It is difficult to damage the nerve bundles even when they are held free in one's fingers and attempts to penetrate them with a needle under direct vision are made.

Ramenti¹¹ reports a fatal case in a man, aged sixty-five years, who was dismissed on the twelfth day after radical operation for hernia, and on the fourteenth day after leaving the hospital developed meningismus with paresis, paraplegia and other symptoms of cord disease, with disassociation of sensibility, septicemia, splenomegaly and jaundice. Death appeared seven weeks after the onset of the symptoms. Devraigne, Suzor and Laennec⁴² described a most interesting experience. Cesarean section was performed upon a multiparous woman of twenty-six because of the presence of a placenta previa. Two c.c. of a 5 per cent novocaine solution were employed. Heaviness of the lower extremities appeared four days after operation. On the following day there was a complete flaccid paralysis of the lower extremities. The knee jerks and the tendo Achilles reflexes, and sensation were absent. The trunk muscles and upper extremities were equally paralyzed. The olecranon and radial reflexes were also abolished and paralysis extended as high as the muscles

of the neck where it was less marked. There was no paralysis of the eye, tongue or soft palate muscle; nor was there any vesical or anal incontinence. Headache was conspicuously absent. The condition was thought to be due to a more rapidly spreading poliomyelitis than that usually seen in the ordinary infectious variety. On the following day, very little paralysis was present, and on the day immediately after, the quadriplegia was almost all gone save for slight weakness of the muscles of the lower extremities. The patient was discharged as cured eighteen days after operation.

Out of a total of more than 1100 cases, Case⁴³ reports one nerve complication which occurred on the service of a colleague, J. M. Nielson. A perineal repair was done on a thirty-six-year old woman. As the anesthesia was beginning to wear off, the patient began to complain of severe pain in the tip of the coccyx and sacral region. This continued unabated for two weeks and was relieved temporarily by heat and not in any other way except by opiates. With the pain there appeared a saddle-shaped area of total anesthesia in the perineum and buttocks, and rectal and vesical insensibility, the patient losing control and becoming incontinent.

When seen two weeks after operation, the foregoing was confirmed; but there was in addition hyperesthesia in the first sacral and second sacral areas on the left and in all the lumbar segments on the right. The lumbar segments escaped on the left; while the first and second sacral segments escaped on the right. The pain was greatly increased by raising the trunk, straining coughing or sneezing. A diagnosis of cauda equinae lesion was made, probably hemorrhagic. Improvement had been steady but slow. At this writing, five weeks after the onset, there is marked sensitiveness in the area formerly totally anesthetic. The other segments have returned to function but the patient walks clumsily. The final healing in this case was complete and there is at present no complaint whatsoever, nor any objective sign of nerve disturbance.

Orth¹² reported no nerve complications in a series of 1400 lumbar anesthetics

and Warnecke²² none in 1500 inductions. A case of paraplegia of the lower extremities as described by Lemoine⁴⁴ is of interest. No anesthesia resulting after the apparently subarachnoid injection of 12 cc. of allocaine for a varicocele operation, he resorted to a local novocaine infiltration. On the same evening, there appeared a paraplegia of both lower extremities, with the sensation of pins and needles in the feet. Micturition was normal. The planter and abdominal reflexes were intact but the knee jerks were absent. On the seventh day after operation anesthesia of the legs was no longer present and motility was almost normal. Lumbar puncture on the second day after operation had elicited a clear spinal fluid with no signs of meningeal irritation.

Bazy¹⁸ operated upon a fifty-nine-year old man for hernia. Soon after operation, the patient complained of pain in the limbs similar to cramps and weariness. Complete loss of sensation in the entire gluteal and genital regions followed. The gluteal muscles, especially, were hard on palpation; nor was their elasticity hardly restored after three years. Increased knee jerks were likewise present.

In a small series, no more than 100, under novocaine anesthesia, Izquierdo¹³ noted 1 instance of paralysis of the lower limbs that lasted for an entire month, 1 case of anal incontinence of a week's duration, and 1 case of marked necrosis. None of these cases were described in detail. Decubitus ulcers have been reported by Bilancioni,⁴⁵ Fischer,⁴⁶ Klein,⁴⁷ and Sudeck.⁴⁸ Nonne and Demme⁴⁹ encountered a case of degenerative myelitis in a man of fifty-nine, operated upon under tutocaine anesthesia, who later expired. Three instances of paralysis of the external popliteal and sciatic nerves were noted in a series of 2207 rachianesthetics by Cotte.⁵⁰ Babcock's experience⁵¹ is particularly interesting. On 11 different occasions, spinal anesthesia was induced in one of his patients without any evidence of nerve injury. In 1 case, however, he produced a marked radiculitis by the

accidental injection of a nerve root. Lee⁵² who has seen no cases of injury to the spinal cord states that Weigelt⁵³ adds two additional cases to two that he had previously reported. Paraparesis occurred in a woman fourteen weeks after spinal anesthesia. This was eventually followed by complete recovery. In the other patient the paralysis followed the intraspinal anesthesia twenty-seven months after its injection, with a fatal ending. Autopsy showed obliteration of the subarachnoid space in the thoracic and lumbar regions. The obliteration was caused by chronic inflammation and fibroid thickening of the meninges. Secondary changes in the spinal cord were due to deficient blood circulation, and to compression. It seems to us that one should be careful before ascribing such a result occurring so long after to the subarachnoid injection.

Organic changes rarely come on in after-life following a previous spinal anesthesia. Occasionally, patients have resorted to the law in an effort to collect compensation on such a basis. According to Evans⁵ only 2 cases appear in the literature where, after careful neurological examination, such a claim, following lumbar puncture, might be justifiable.

Direct injury to the cord may be occasioned by high injections. In the 496 cases cited under meningitis reported from a local hospital there was one fatal paraplegia following an intraspinal anesthetic administered between the eleventh and twelfth dorsal vertebrae. It is, therefore, of interest to recall that Jonesco⁵⁴ the foremost exponent of high injections, puncture being practiced at a level as high as the cervical region, has experienced no serious sequelae and no complications in 6200 rachianesthesias.

Three years ago, we did a tracheloplasty, perineorrhaphy, Simpson-Gilliam ventral suspension of the uterus and appendectomy on a twenty-six year old patient. Eight days postoperatively, she developed a weakness in her left quadriceps femoris group which became progressively worse so that, two weeks after operation, she

could not raise her leg off the bed. She could not walk for three months. Finally, power was slowly restored to the muscles and at the end of a year, her thigh was as strong as before the operation. In our opinion this complication was due to a nerve root injury occasioned during the spinal tap, despite contrary opinion advanced by consultants, who believed the condition to be due to unexplained trophic disturbance.

We have had 2 other cases of weakness of the quadriceps group lasting only four to five days.

There have been occasional cases of tingling of the lower extremities, anesthesia of the buttocks, itching about the anus, all lasting less than three days. None of these complications presented any serious aspects.

PSYCHIC DISTURBANCES

Much has been written concerning the psychological aspect of spinal anesthesia. Indeed, some authors object to any form of anesthesia, not excluding spinal, which allows the patient to retain consciousness during the operative procedure. This does not apply, of course, to some minor condition for which the public has been taught to expect local infiltration.

Lee⁵⁵ in discussing Schultz' report of 2251 cases from the Lankenau Clinic refers to his experience in the Department of Mental and Nervous Diseases, of the Pennsylvania Hospital, where the mental chaos of certain types arising during an operation under some form of local anesthesia has been followed by various grades of mental catastrophe.

Izquierdo¹³ mentions 1 case of insanity that cleared up completely after a month's duration. A case of postoperative psychosis was reported by Bianchi⁵⁶ that occurred in a young man who had been a hard drinker. Following a herniotomy, an acute psychosis with hallucinations set in and lasted for two weeks. Such a sequel to operation, however, has been encountered under other forms of anesthesia among patients long addicted to the use (or, rather, abuse) of alcohol.

Our experience has revealed very few instances of psychic aberrations following spinal anesthesia. One case stands out clearly in our memory, to wit, a young man, thirty-two years of age, operated upon for a floating kidney. He had been markedly apprehensive over his condition for months before submitting finally to surgical intervention. Having discussed spinal anesthesia with several of his friends who had been operated upon by this method, he did not approach the event with any undue fear. While he was in the hospital, complete collapse of his left lung appeared but cleared up entirely before discharge. Shortly afterwards, he began to complain of a sensation of water running down along his right side, the site of the nephropexy, from the upper margin of the wound down along the right lower quadrant of the abdomen and along the anterior and inner aspects of the right thigh. A thorough physical examination which included several complete genitourinary and neurological investigations failed to reveal any organic cause for the paresthesias of which he complained. At the present date, approximately six months after operation, he still feels these sensations at frequent intervals and has become a well developed hypochondriac, indeed, to such an extent, that he is unable to maintain a steady rate of employment. Lately, we occasionally encounter a psychosis after spinal anesthesia; but only in neurotic or apprehensive patients who have received sodium amytal intravenously previous to operation and in whom the psychosis is directly referable to the sodium amytal. At times, delirium, hallucinations and an acute maniacal state result, to disappear completely within a few days. From straight spinal anesthesia, however, with the exception of the case cited here, we have had no psychic disturbances.

Another possible complication is that resulting from the application of heat to the lower extremities after the patient is returned to bed and before the anesthesia disappears. In one of our cases a

hot water bag so applied produced a serious burn of the plantar surface of the foot.

Occasional instances of coma (Coulin)⁵² and of recurrent syncopal attacks (Izquierdo)¹³ have been reported in the literature.

Pulmonary complications following spinal anesthesia are certainly less frequently encountered than after inhalation narcosis. From January 27, 1929 to September 23, 1929 we operated on 1819 patients. Of these 1010 were done under spinal anesthesia. The remainder belonged to the type of minor operation in which it was not deemed worth while to enter the subarachnoid space, to wit, incision of subcutaneous abscess, excision of sebaceous cysts and superficial lipomata, and the like.

In these 1010 cases which incidentally remained in the hospital ten days or more, there developed 3 cases of pneumonia, 11 of bronchitis, 4 of dry pleurisy, and 1 massive collapse of the lung. There were no fatalities. These cases were collected during the summer and winter months and represent a fair average of weather conditions. Compared with the report of Cutler and Hunt⁵⁸ in which 55 pulmonary complications with 11 deaths were noted in 1562 operations under inhalation anesthesia, spinal anesthesia seems preferable.

If there be anything in the hypothesis that inhalation anesthesia by its irritating effect on the tracheobronchial mucosa predisposes to pulmonary infection, block anesthesia is certainly indicated in order to lessen lung complications.

In reviewing the postoperative experience of a large number of patients operated on under this form of anesthesia one is struck by the comparatively slight amount of nursing care necessary to keep them comfortable. From this standpoint alone, one receives the decided impression that spinal anesthesia is followed by fewer annoying sequelae. On the whole, the relative values of spinal and inhalation anesthesia can be gauged only by clinical impressions gleaned from a comparison of an extensive series of cases. Our opinion needs no further expression.

PERITONITIS FOLLOWING ABDOMINAL SURGERY*

JOHN B. DEEVER, M.D.

PHILADELPHIA, PA.

POSTOPERATIVE peritonitis is a contingency that should not be allowed to occur, but like many things that ought not to be, it will occasionally happen. It is only natural that we ask ourselves, Why? Following abdominal surgery peritonitis may result from infection present before the operation or it may be due to the operation itself; in other words, either an external or an internal factor or both factors may be responsible for this undesirable postoperative event.

Let us first consider the external factors. These may be summed up in the words aseptic technic or rather the lack of it. As we all know, the instruments and the hands of the operating staff may be the source of bacteria and the agency of their dissemination. These factors are avoidable by careful technic. It goes without saying that all instruments, gauze, ligatures, etc., should be aseptically prepared and should be kept sterile. In the Lankenau Clinic we have a detective in the person of the bacteriologist who at any time and as often as he wishes takes smears and cultures of the hands of the operating personnel from the surgeon down. In fact there is a pleasant rivalry among us as to the best record for this personal asepsis.

The second external factor is the skin of the abdomen of the patient. Staphylococcus we know is always present in the skin and is not an infrequent finding in postoperative peritonitis. Therefore an essential part of operative asepsis is careful preparation of the patient. These are mechanical factors. They are controllable and should never be the cause of postoperative peritonitis. But not all external factors are mechanical and controllable: for example, penetrating wounds of the abdomen. While proper technic, as a rule, provides against this type of infection, it cannot always be controlled since much depends upon

the conditions prevalent at the time of the injury. But naturally every effort must be made to get as aseptic an operative field as circumstances permit.

Now as to the intra-abdominal factors, or infection present at the operation. This comprises the main point of our discussion. As a rule the infection resides in the operative field and its vicinity. It may however reside in a distant focus. The defensive mechanism of the body may be so weakened by disease that organisms from a distant focus may be released by the operative act and find a fertile soil in the peritoneum. The lesson carried by this possibility is preoperative attention to oral hygiene, the respiratory tract, etc., in fact all precautions that make for safe surgery. The local intra-abdominal sources for possible dissemination are numerous and varied. I need but mention two of the more common ones: encysted collections of pus from an inflamed appendix or from a pelvic abscess. The prevention of peritonitis in these cases is both a matter of diagnosis and of operative technic. Preoperative determination of the presence of an abscessed appendix should lead the surgeon to take the first step in preventing contamination by making the proper approach, an extraperitoneal approach when this is possible. In fact in all recognized infected cases the incision should be so planned as to enable the surgeon to deal with the infected focus without invading healthy tissue. This means also the proper placing of gauze pads, using sheets of rubber dam, providing proper drainage, etc. There are, of course, no rules for these procedures. Their use is a part of surgical judgment and their efficiency is established by the high or low incidence of postoperative peritonitis in the records of each individual surgeon.

An encysted collection of pus in the

* Submitted for publication, April 8, 1930.

majority of cases of appendicitis fortunately is in the lower right abdomen, and can be evacuated by an extraperitoneal approach; where the collection is high up, lateral and posterior to the base of the cecum and colon, the extraperitoneal incision, carried well out and dividing the muscles in the line of the skin is also less likely to be followed by postoperative peritonitis than when the incision is made over the most prominent part of, or mesial to the swelling. After the abscess cavity has been evacuated and no rivulets of pus are seen emptying into the cavity, and the appendix is neither visible nor palpable, nothing more than drainage of the cavity should be done. It is our practice to pack the cavity lightly with loose gauze wrung out of a 1:20 carbolic acid solution. When the appendix can be seen and felt and can be removed in its entirety without danger of breaking through the limiting wall that separates it from the preperitoneal cavity, it is removed and the cavity packed with loose gauze. When the limiting wall is broken through and especially if there is a small amount of pus at the base of the appendix, the cavity is packed at once, and after separating the parietal from the visceral layer of peritoneum around the inner circumference of the cavity, we lift up the abdominal walls and the underlying parietal peritoneum, introduce a large sheet of rubber dam and follow this by the introduction of one or more large abdominal pads and smaller pads, if necessary, to wall off and thoroughly protect the surrounding peritoneum. The appendix is then removed and the cavity packed. This is frequently done in our clinic with good results, which means no postoperative peritonitis, and as a rule recovery. Where the walls of the encysted collection are made up entirely of coils of small intestine, the risk of subsequent peritonitis is greater. If we are able to recognize the condition we hesitate to do an early operation.

In case of a pelvic encysted collection, if it is low down the incision is made, in the

male through the rectum, and in the female through the roof of the vagina, posterior to the cervix. If the pelvic collection is located in the median line the incision is made above the pubis after the bladder has been emptied by catheter. In a pelvic abscess resulting from disease of the uterine appendages, the approach is best made through the vagina. But if there is any uncertainty about the state of affairs, that is, if there is danger of puncturing a coil of bowel, we open the abdomen in order to ascertain the topography and then make the approach through the vagina and close the abdominal wound.

A potential cause of postoperative peritonitis is found in operations on the intestinal tract in which the gut, with its rich bacterial content, has to be incised. Here also the careful planning of the operation and meticulous care to avoid contamination by spilling the intestinal contents will prevent the undesirable postoperative complication we are discussing. In operating an intestinal obstruction when one is not absolutely sure that the obstruction has been relieved there should be no hesitancy in turning out the entire small intestine so that it and the large intestine can be thoroughly examined. No harm need accrue from the procedure provided the operative field is sterile and the intestines are well covered with large warm gauze pads.

The foregoing are some of the more common causes of peritonitis after abdominal surgery. They can be recognized before or at the operation and with judgment and technic can, to a large extent, be so handled as to provide for an aseptic recovery. There are, however, a few potentialities which cannot be foreseen. Fortunately, they are rare. Among these may be mentioned an infected blood clot as in a ruptured extra-uterine pregnancy. In these cases it is always our practice to cleanse the peritoneal cavity of blood clots. Failing to do this runs the risk of the clot or clots becoming infected by migration of microorganisms through the walls of

the intestine. This applies likewise to intraperitoneal hemorrhage from any cause. Other cases may be attributable to overlooked intestinal obstruction due to incomplete primary operation for obstruction. For example, snaring of a knuckle of bowel into a rent in the mesentery, or into a congenital hole, or a loop of bowel that has become engaged between the margins of the opening in the transverse mesocolon through which the stomach is drawn in making a posterior gastroenterostomy and where the lesser peritoneal cavity has not been completely closed, when stitching the margins of the opening in the transverse mesocolon to the wall of the stomach immediately above the anastomosis.

Bile leakage after gall tract surgery causing a bile peritonitis also occasionally occurs and sometimes can be traced to unrecognized anomalies of the bile ducts; or to slipping of the ligature in the cystic duct, or to incomplete closure of the gall bladder bed after cholecystectomy. These are favorable cases for re-operation if not allowed to linger too long.

With these briefly stated facts in mind, it is easy to recognize that abdominal surgery has its pitfalls, which in most instances, however, can be avoided. It is a trite saying that the best way to treat postoperative peritonitis is to prevent it.

As already indicated the most important step in the technic of abdominal surgery where infection is present is to avoid contaminating the peritoneum around the infected area. This is the surgeon's greatest concern. What is the best way to guard against spreading infection? First, its recognition by inspection, color and odor; secondly, by taking smears of the area around and distal to the operative field, having them examined and immediately reported upon. This takes but a few

minutes, provided the proper equipment is at hand, which includes above all a competent bacteriologist working in a room adjoining the operating theater. This is one of the operating surgeon's greatest assets. I realize that this equipment is not always at hand, but that fact does not alter the desirability of having it. The report of smears of the area distal to the site of infection is a guide as to how far to carry protection, as well as to the amount and kind of drainage to use and where it is to be placed so as best to serve its purpose.

If in the absence of these precautions or in spite of them, peritonitis does set in, the treatment is the same as for the preoperative inflammation, that is, providing for localization by the usual measures of complete anatomic and physiologic rest and re-operating at the most opportune time. While some surgeons advocate immediate re-operation, this is not our practice, except where the operation has been done for a visceral injury. If, as sometimes happens, the patient on the first or second day appears not to be doing well, prompt re-operation is indicated. By not doing well, we mean, of course, presenting the usual signs and symptoms of peritonitis, rigidity, hyperperistalsis, tenderness, etc. With the patient under the careful constant observation of a well-trained interne, the time for operation can be better seized than in the preoperative case when peritonitis has, as a rule, already set in when the patient is brought to the hospital. While the postoperative case has this advantage, it labors under the great disadvantage of the effects of the first operation and it is only by superhuman efforts and good fortune that recovery takes place. Therefore the trite dictum cannot be too often repeated: The best way to treat postoperative peritonitis is to prevent it.

CONCEALED HEMORRHAGE FOLLOWING OPERATION

DIAGNOSIS AND TREATMENT*

CHAS. GORDON HEYD, M.D., F.A.C.S.

NEW YORK

HEMORRHAGE following laparotomy is fortunately an infrequent complication. The precision of technical procedures and more accurate diagnosis have lessened the possibilities of post-operative hemorrhage. It is, however, still a complication of magnitude and one that should be considered after some types of abdominal surgery. There are certain complications which occasionally follow any kind of laparotomy: shock, gastric dilatation, hemorrhage, cardiac failure and embolism. These are directly due to anatomical causes and when they occur within the first twenty-four hours after operation are sudden and tragic. During the second twenty-four hours, concealed hemorrhage may well be a possible complication and still later hemorrhage may occur as a secondary development of abdominal sepsis. True shock is, however, rare. At the present time the infrequency of shock is due largely to the preparation of the patient by means of a dry technic rather than by the prolonged washing and scrubbing of former days when the patient frequently lay in a pool of wash water and suffered varying degrees of bodily refrigeration.

Bleeding into the abdomen after operation, where the abdominal wound has been sutured without drainage, is almost invariably associated with intense abdominal pain. The escape of blood into the peritoneal cavity induces very definite clinical signs of chemical peritonitis. There is more than the accustomed postoperative rigidity, the abdomen is fixed and the patient can accurately localize the area of pain because it is due to the escape of fluid into a localized portion of the abdominal cavity.

After certain types of operation, particu-

larly where gauze drainage has been employed, such as the tamponage of the bed of the board ligament after removal of an intraligamentous cyst or from the parenchymatous oozing that comes with the evisceration of an inflammatory mass, there is the rapid loss of body fluid as the result of serum drainage and the clinical condition resulting therefrom is very apt to simulate hemorrhage. The patient is somewhat pallid, the pulse is rapid and in a cursory way the clinical picture does suggest the general appearance of the patient who is suffering from intra-abdominal hemorrhage. This condition, however, should not be confused with hemorrhage. The patient has a tachycardia from loss of body fluids, but there is no change in the blood color or in the red cell count. Furthermore if the gauze drainage is pinched between the thumb and first finger there will be a moist impression with no cobweb-like fibrillae of fibrin formation. If there is a real loss of blood upon pinching the gauze between the fingers there will remain upon them cobweb-like fibrillae of fibrin and blood.

Hemorrhage as a postoperative complication may be roughly divided into two great groups: (1) cases in which hemorrhage may be occasionally expected or anticipated, and (2) cases in which hemorrhage is not to be expected or anticipated. Surgical intervention in the right upper quadrant in which the pancreas may be infected or injured are operations that contribute par excellence to the liability of hemorrhage. There is an increased tendency for hemorrhage in any disturbance of the pancreas on account of the unusual blood supply but more particularly from the escaped pancreatic juice with its

* Submitted for publication April 23, 1930.

marked lytic properties causing erosion of adjacent or contiguous blood vessels. Whenever jaundice is present there is always the possibility of concealed hemorrhage. It is noteworthy that after operations on the common duct there is a distinct tendency for this complication to occur. The effect of jaundice is essentially chemical, not infectious, and hemorrhage is one of its most frequent manifestations. It is interesting to note that in approximately 75 per cent of the cases that die after operations on the common duct there is found at autopsy an intra-abdominal collection of fluid blood varying from 300 to 800 c.c. and in fully half the cases where death takes place postoperative hemorrhage is an important factor in the production of death.

There is also an increased element of intra-abdominal hemorrhage after hysterectomy, after enucleation of tumors from the bed of the broad ligament. The hemorrhage that sometimes ensues after hysterectomy is usually rapid, characterized by very great escape of blood and the clinical signs of hemorrhage are dramatic and rapid. In the hemorrhage that occurs from oozing from the bed on the broad ligament or after enucleation of inflammatory masses, there is apt to be capillary bleeding from many bleeding points which individually are negligible but which collectively represent a great loss of blood. This type of bleeding occurs from raw areas of intestines, or where large portions of the peritoneum have been denuded as in the separation of inflammatory or postoperative adhesions. Let it be remembered that the omentum contains no muscle tissue and every bleeding point on the omentum is apt to continue to bleed unless it becomes adherent or agglutinated to adjacent peritoneal surfaces or ligated.

The diagnosis of concealed hemorrhage rests upon the ascending pulse rate. In all laparotomies where there is the possible chance of hemorrhage being a factor, such as gastroenterostomy, resection, hysterectomy, enucleation of intraligamentous cyst,

anastomotic operations on the bowels, operation in the presence of acute inflammatory tissue, a very excellent precaution is to take half-hourly pulse determinations and have them charted; an acceleration of the pulse rate from half hour to half hour, over a period of time, is especially significant. A successive fall in the red blood count and in the hemoglobin are of value when hemorrhage is suspected but it will seldom be carried out as a routine postoperative measure.

After almost all clean cases of abdominal surgery there is a rise of temperature for the first twenty-four to thirty-six hours. This is a natural reaction, representing the so-called surgical, traumatic or operative fever. There is a definite parallellism in the relationship between temperature, pulse and respiration. Theoretically, for each degree of fever one can expect an increase in the pulse rate by ten, an increase in the respiratory rate by two, and this parallellism is ordinarily preserved. If hemorrhage in any great degree has taken place there is a loss of this definite parallellism and the pulse rate is increased out of all proportion to the temperature.

The symptoms of concealed hemorrhage will largely depend upon the rapidity of blood loss. If the blood loss is continuous but slight the transition from a condition of comparative well-being to that showing a typical picture of hemorrhage will be by such easy stages as to deceive the observer unless he has in mind the possibility of bleeding. Of outstanding importance is the gradual continuous and progressive increase in the frequency of the pulse. The pulse in hemorrhage is quick, shows less volume and there is a peculiar snap as each pulse beat impinges upon the examining finger. The respirations are invariably shallow and frequent, with a suggestion of air hunger, although I have seldom seen marked air hunger. The skin is moist, owing to a lack of vessel tone. There is a distinct change in the color of the patient. The patient is not only pallid but there is a pearly-like tint to the sclera, the facies has

an expression of acuteness and alertness: there are purposeless movements of the arms and legs but as a rule not of the body. The patient subconsciously restrains body movement in the desire to obtain the greatest amplitude of inspiratory respiration. There is a distinct loss of surface heat and the patient complains of an inexpressible sense of weakness.

The first and most outstanding question to be answered: is the hemorrhage continuing or is it stopped? Are we dealing with a single massive hemorrhage, dangerous to be sure, but arrested, or are we having a continuous and continuing hemorrhage? The type of operation and the pathology exposed at the operation very often will help in the consideration of this question. The bleeding from a gastroenterostomy is apt to be interrupted and repetitive, while bleeding from a single large vessel, such as the broad ligament, is apt to be continuous and a lethal termination occur within a relatively short time.

The essential element in the treatment of any hemorrhage is to stop the bleeding and the best time and place to stop bleeding is at the time of the operation. No patient should be returned to bed while the possibility of hemorrhage is still present. The question whether transfusion should be employed and when, is a question requiring nicety of judgment. To give a patient who has been almost bled white a transfusion is oftentimes the cause of fresh bleeding, with a sudden collapse and death. If the patient suspected of having concealed hemorrhage and in whom the diagnosis is reasonably sure has a pulse that is well maintained although rapid, it is many times wiser to watch the patient and allow the bleeding to be more fully arrested than to give an immediate transfusion. At the end of eight to ten hours give a small transfusion and two days later make up for the blood loss by a larger transfusion.

The loss of blood into the abdominal cavity represents not only a loss of the cellular elements of the blood but a great loss in the fluid volume and since the heart

requires a certain periphery resistance to maintain circulation fluid should be administered to the patient by practically all avenues, skin, mouth, vein or rectum, unless there are local reasons against the employment of one or the other. In surgery in the upper abdomen, or of the lower abdomen not involving the colon, proctoclysis of tap water with 10 per cent glucose should be instituted. If the operation has been pelvic, water by mouth in the absence of vomiting should be given and hypodermoclysis in all cases. The intravenous introduction of normal saline is associated with some of the dangers outlined here for transfusion, but not all. If however, the patient is in extremis from actual blood loss transfusion must be done immediately as there is a point beyond which patients cannot bleed without dying and the risk of activating the hemorrhage from transfusion must be accepted in order to keep the patient alive and to allow reopening of the abdomen for hemostasis.

If the surgery has been in the nature of gastric resection or a gastroenterostomy the bleeding will be into the stomach and the patient will vomit a greater or lesser quantity of blood sometime after operation. When surgery has been performed on the large bowel the presence of blood in the bowel lumen below the point of anastomosis will invariably stimulate bowel peristalsis with the evacuation of a fluid stool or a soft stool of fresh blood or partially oxidized dark blood. The bleeding that occurs into the stomach after a gastroenterostomy or resection very soon establishes a vicious circle. The more bleeding that occurs the greater the distention of the stomach and the greater the distention the more apt is bleeding to continue. The introduction of a stomach tube through the mouth or a Levine tube through the nose and the evacuation of all of the blood from the stomach is one of the best means of stopping gastric hemorrhage for it allows the stomach to contract and by contraction lessens the liability of further bleeding. We have practically never seen

harm result from a carefully introduced stomach tube, even as recently as two hours after a gastric operation, provided the stomach contents are aspirated and not removed by lavage.

The elevation of the foot of the bed has a decidedly beneficial effect in keeping the diminished blood volume in circulation and by providing more adequate blood supply to the already anemic brain centers. Morphine in sufficient doses to quiet the patient and render the patient less acute is indicated. The application of external heat is highly desirable but great care must be exercised in the prevention of burns. The normal patient may tolerate a hot water bottle applied to the body with impunity but which if applied to a patient suffering from hemorrhage a lesser degree of heat is sufficient to produce extensive burns.

The decision to reoperate a patient suffering from concealed hemorrhage is always a difficult one; the natural hope of most surgeons is that the bleeding has stopped and if arrested nursing and adequate postoperative care will safeguard the patient. There is a time, however, when difficult as the decision is it must be made, as failure to reoperate for concealed hemorrhage before it is too late is tantamount to robbing the patient of any expectation of being saved.

At the present time postoperative concealed hemorrhage is fortunately so infrequent that this decision comes but rarely even in an extensive surgical practice, but it does occur and it is our observation that the decision to reoperate is many times too long delayed. If the decision to reoperate is made an immediate transfusion should be given and the moment the transfusion is terminated, the wound should be reopened and the field of the previous operative procedures carefully canvassed. The technical procedure of operating in a

field infiltrated with blood, and one that a short time before has been operated upon, is no easy matter. Here again the type of surgery suggests the most probable cause of the bleeding: bleeding after cholecystectomy is obviously either from an incompletely ligated or a loosened suture on the cystic artery, for bleeding from the bed of the gall bladder is ordinarily not of sufficient magnitude to require reoperation. Packing around an untied cystic artery is not apt to be successful as the control of hemorrhage from this vessel always requires ligation. If a gastroenterostomy suture line is suspected of bleeding, or the site of anastomosis between stomach and intestine, an anterior gastrotomy with partial evisceration of the inside of the stomach is the easiest and quickest way to apply direct ligation to the bleeding point and is satisfactory, while the taking down of an anastomosis will seldom reveal the actual bleeding point and will require every detail of the original operation to be reenacted.

Bleeding from soft tissue beds, paranchymatous bleeding or hemorrhage from separated adhesions, requires packing. The operative field is carefully quarantined by placing sheets of sterile rubber tissue about the area and into this barricade, so to speak, sufficient sterile gauze is introduced to maintain adequate pressure for hemostasis.

After reoperation for hemorrhage all of the measures of combating shock and blood loss should be carried out. As long as the pulse is regular, although very fast, the surgical policy should be: rest, fluid replacement and no stimulation. There is a period of a few hours after operation when a wise and masterly inactivity, with a therapeutic courage to just maintain the patient, is far better than unwise measures aimed at stimulating the patient.

PREVENTION OF ABDOMINAL ADHESIONS*

J. F. BALDWIN, M.D.

COLUMBUS, OHIO

THE prevention of postoperative adhesions depends entirely on the prevention of inflammatory reaction and in cases in which denuded surfaces are produced by the operative procedures, or in which preexisting adhesions are separated during operation, on the peritonealization of all such surfaces. If, in spite of every care, postoperative adhesions seem to be inevitable, then every effort should be made to adjust the intestines in such a way that these adhesions will not result in ileus.

Anything which bruises, abrades or irritates peritoneal surfaces predisposes to sufficient inflammatory reaction to produce adhesions. All rough handling, therefore, the catching of peritoneal surfaces with tissue forceps or clamps, or the use of irritating antiseptics like tincture of iodine, should be avoided. Dry sponges and wipes readily produce such injury and for that reason should never be used in the peritoneal cavity, but only warm moist sponges. Moist sponges are also greatly superior to dry in absorbing blood and other fluids; the advantage of such moisture was emphasized by earlier writers who spoke of such sponges as greedy; but this advantage has been largely lost sight of by modern operators. Moistening the wipes and sponges with normal salt solution instead of ordinary sterile water may perhaps render them less irritating, but that has not been demonstrated and the difference could certainly be but slight. (Some ambitious student or interne might perhaps make a study of this by animal experimentation and thus produce an interesting thesis.)

Any foreign matter in contact with peritoneal surfaces, like a cigarette drain or rubber tube, necessarily produces a degree of trauma which predisposes to

adhesions, and if left long in contact will infallibly produce them; hence when it is at all possible such drainage should be protected by being placed in contact with some fixed portion of the bowel, as the colon, or by the judicious interposition of the omentum, supported as necessary by a few stitches. This applies particularly to drainage of the gall bladder stump, which can be secured by pulling up the omentum and tucking it in between the liver and the transverse colon, fixing it in place by a few catgut sutures.

Drainage in an appendix operation is frequently necessary, but should almost invariably be secured through a stab opening far over to the right, and with the drainage itself so adjusted if possible, *by the fingers still on the inside of the abdomen*, that the omentum and cecum are utilized to prevent contact with the small intestines. The main incision can then usually be closed completely.

If on opening the abdomen preexisting adhesions are found, these should not be separated unnecessarily if they are so placed and of such a character as to offer no obstruction to peristalsis. Only such adhesions should be separated as are necessary in order to remove the pathology for which the operation is instituted. After the operation is completed every effort should be made to cover over all raw surfaces. This can frequently be done, if necessary, by rolling the affected loop of bowel upon its axis so that the raw surface is brought into contact with its own mesentery. A few stitches can then be inserted to hold it in position and thus there will be no raw surfaces exposed. Sometimes adjacent loops of bowel, each with a raw surface, can be adjusted to each other so as to safely bring the raw surfaces in contact, but care must be

* Submitted for publication, April 8, 1930.

exercised that there is no space left underneath this union for the entrance of a free loop of bowel which would thus be liable to strangulation. The possibility of using the omentum in all these maneuvers should not be lost sight of, since it seems to have been developed for just such emergencies. Sutures should be of very fine silk or of fine plain or chromicized catgut, and should be inserted with great care and with the avoidance of all unnecessary exposure. It is of prime importance to avoid all tension.

The greatest liability to adhesions, however, occurs in the pelvis after operations for old inflammatory troubles which have resulted in extensive adhesions the separation of which may leave the entire surface of the true pelvis denuded. If nothing is done to protect this the omentum and small bowels will drop in and will inevitably form adhesions with resulting liability to postoperative ileus or other serious complication. This raw surface can always be completely peritonealized by making a free opening into the vault of the vagina at the completion of the operation, or leaving the upper end of the vagina open if the womb has been removed, and passing into the vagina the ends of two or three strips, according to the needs of the case, of washed iodoform gauze, the rest of the

strips being lightly placed in the pelvis as a fluff. The sigmoid is then swung around over this fluff and attached by continuous suture to the edge of the peritoneum at the brim of the pelvis. Good judgment should be used in bringing this around to see that there are no angulations produced as the stitches are inserted. In very rare cases the sigmoid is not quite sufficient, and then the space on the right can be filled by mobilization of the cecum. The omentum is then smoothly placed over the mobilized bowel and the incision closed. The gauze fluff should be removed after the lapse of one week, by catching the ends of the strips in the vagina. By that time their removal is almost or quite painless and if the opening has been made of proper size, there is no need of any replacement of the gauze. Vaginal douches should be used after removal of the fluff as needed for cleanliness. The sigmoid soon sinks down into the pelvis and thus makes a complete floor. There has been no raw surface exposed at any time.

Great care should be exercised in closing the abdominal incision to see that the edges of the peritoneum do not come in contact with the underlying intestines or omentum. The peritoneum should be closed by a running catgut stitch, with the edges carefully turned out so that such contact can be absolutely avoided.

POSTOPERATIVE INTESTINAL OBSTRUCTION*

G. D. DELPRAT, M.D., F.A.C.S., AND ALANSON WEEKS, M.D., F.A.C.S.

SAN FRANCISCO, CALIF.

THE causes of intestinal obstruction in the non-operated abdomen are few. It is true that malignancies (principally carcinomas) of the intestine are apt to occur toward late middle life and early senescence, and that congenital anomalies, volvulus and intussusception must be considered in the diagnosis of intestinal obstruction in early life. During the major part of adult life, however, obstruction of the intestine is a rare occurrence except in these persons who have been subjected to an abdominal operation. Before the days of abdominal surgery, strangulated herniae occupied a similar position of importance as a cause of intestinal obstruction in adult life. In backward communities, where reducible herniae are neglected, operations for strangulated herniae are very frequent. Mission surgeons returning from Africa report a surprisingly high incidence of herniae among the natives, most of which sooner or later become strangulated.

In 88 cases of the authors, of intestinal obstruction during the last few years, in which operation was necessary, 32 cases had had some surgical interference in the abdomen. In this paper, however, the occurrence of intestinal obstruction will be considered as a postoperative complication, and only those cases discussed where the obstruction occurred during the patient's stay in the hospital, or happening a very short time after the patient's discharge from the hospital.

The cause of intestinal obstruction (postoperative) is the formation of adhesions either in the form of "fiddle-strings," broad bands, or the plastering together of loops of intestine with angulations or twists. The final cause of adhesions is obscure and their prevention even more elusive. No one has been able to explain why one simple clean case should be

followed by adhesions that obstruct, and another case where extensive manipulations are necessary remain free from symptoms. The plea of "gentleness in handling tissues" should always be made, but it is by no means the whole story. Case II came to operation with a three liter multilocular ovarian cyst. With the patient in the Trendelenburg position a low, midline incision was made, and the cyst found immediately below. A trochar was inserted and enough fluid withdrawn to allow the cyst to be delivered from the abdomen. There were no adhesions between the cyst and adjacent organs. The intestines, from the patient's position, were well up in the abdomen and no packing or handling was required. The cyst pedicle was clamped, ligated, sutured, peritonealized without the slightest difficulty, leaving a single small suture line, but to this later became attached the sigmoid colon so firmly in five days that obstruction developed which required surgical relief. It is difficult to imagine an operation on the abdomen where there was less tissue manipulation, and yet how many more serious cases escape this complication.

Another interesting, but most distressing group is the so-called plastic peritonitis case. Here extensive adhesions form between adjacent loops of intestines along varying areas of their contiguous surfaces. This condition is clearly beyond the control of the surgeon, but yet he is faced with the burden of repeated operations. One such case has been operated on four times. In another such case the filmy, sticky adhesions could actually be seen to form on the operating table. This patient developed a second obstruction within a few months, which required operative relief. No chemical or other treatment of value has been found to treat this condition.

* Submitted for publication, April 23, 1930.

Considered as a postoperative complication it is first necessary to differentiate intestinal obstruction from paralytic ileus. Both conditions are apt to be associated with abdominal distention, tympany and vomiting. An absolute distinction cannot be made because paralytic ileus implies a functional obstruction. But distinction must be made between cases that are to be treated as outlined below for (a) ileus and (b) intestinal obstruction.

As a general rule the later onset of ileus can be predicted at the time of operation. Where abdominal infections have been stirred up, or where there has been undue handling of abdominal organs or intestines, one may confidently expect (and is seldom disappointed) paralysis of the intestine which lasts a varying period of time. Clinically, the patient shows increasing abdominal distention commencing twelve to twenty-four hours after the operation. The abdomen becomes tympanitic and tense. The abdominal muscles feel rigid, but this apparent rigidity is really due to the intra-abdominal pressure. No visible peristaltic waves are seen, and with the stethoscope no borborygmus is heard. Auscultation of the abdomen with the stethoscope is an extremely important part of an examination but is frequently omitted. As the distention increases the patient becomes dyspneic from interference with the movement of the diaphragm. The patient becomes cyanotic from cardiac embarrassment. There is usually a cold, clammy perspiration and the patient has an expression of anxiety and apprehension which may well be reflected in the faces of his attendants. In a short period of time emesis of a small quantity of dark fluid may occur. This is usually the indication for the passage of a stomach tube, which reveals the fact that a large amount of dark, foul-smelling intestinal contents distend the stomach.

It has been noted frequently by the senior author that in these cases the general appearance of the patient (aside from the abdominal findings) bears a

close resemblance to that of toxemia from infections of various anaerobic organisms. It has been shown that numerous organisms of the anaerobic group are to be found in the average normal individual. The rapid multiplication of these organisms in a stagnant intestine vitiated by a depressed circulation, would not be surprising, nor is it unlikely that the toxic products of the growth of these organisms has a profound influence on the general condition of the patient.

The clinical picture of a typical postoperative intestinal obstruction is shown in Case III. After a period of uneventful convalescence which may be as short as four days, the patient may suddenly complain of severe, agonizing abdominal pain. The onset of pain may be of startling abruptness. In Case V, the pain came suddenly enough to interrupt a sentence and clip a word in two. Such severe pain is usually of short duration, giving way to a general soreness in the upper abdomen or about the incision, which in a few minutes reaches a crescendo of acute pain. Paroxysms of pain follow one another with definite regularity. Immediately preceding the acute period of pain, peristaltic waves are to be seen in some cases, and even during the quiescent periods, a stethoscope on the abdomen reveals the boiling within. Very soon after the onset of the pain the patient vomits, first the gastric contents and then green, bile-stained, mucus. At first there is usually no abdominal distention. These symptoms are definitely indicative of small intestinal obstruction and immediate treatment is imperative.

Postoperative obstructions involving the colon, and especially the sigmoid as in Case II, are marked by less startling symptoms. Pain may be a less prominent symptom and its paroxysmal character only elicited after careful questioning. Even if this pain is overlooked suspicion of an obstruction must be aroused by the interruption of the fecal stream. Perhaps no other fact alone illustrates as clearly

the need of care of the toilet of the colon in postoperative cases. Vomiting is always a late symptom in obstruction of the colon. Distention, gradually increasing in extent is the rule, but associated with it is an active peristalsis which sometimes may be seen but always may be heard with the stethoscope.

If these symptoms supervene on about the ninth or tenth postoperative day one must be suspicious of a fecal impaction. Each postoperative case should be given an enema every day unless a satisfactory spontaneous evacuation has occurred: in spite of such a "standing order" it occasionally happens that fecal matter is allowed to accumulate and become inspissated, particularly if the intestinal activity has been slowed by morphine. This condition can be ascertained from the clinical notes and occasionally the impaction can be felt through the rectum. The treatment is obvious. This never occurs if the funnel drip is used.

In the treatment of paralytic ileus and intestinal obstruction it is necessary first of all to detoxicate the patient. This can best be done by intravenous injections of 10 per cent glucose. If there has been considerable vomiting the glucose is given in normal salt solution, irrespective of whether there is a decrease of the blood chloride. A liter of this solution is given twice a day. Intramuscular injections of glucose should not be given in a concentration of over 5 per cent. We very rarely give glucose by this method.

Patients showing abdominal distention due to a paralysis of the intestine are further treated by large hot abdominal compresses and almost continuous flushing of the colon with normal salt solution. Between the frequently repeated colon flushings the funnel drip remains in operation. Enemas of milk and molasses are occasionally given, and to be efficacious these should be of 1000 to 1500 c.c. volume. Injections of surgical pituitrin (1 c.c.) are occasionally given, but the use of drug as a routine is not to be recommended. If the slightest sus-

picion exists of the presence of an organic intestinal obstruction the use of pituitrin is absolutely contraindicated. Gastric lavage should be practiced early before the patient begins to vomit. The removal of gastric contents gives great relief, and the stomach should be kept empty. This may be done by passing a duodenal tube which is left in the stomach and through which irrigations with normal salt are made every thirty minutes. In some cases we have employed the Cornell continuous suction. It is rarely necessary to subject the patient to jejunostomy for the relief of this condition. The incision and drainage of loops of lower small intestine serves to collapse only the loop that is drained, but as a therapeutic measure is useless.

With the sudden postoperative appearance of symptoms of intestinal obstruction immediate operation is indicated. Case v was operated on two hours after the onset of symptoms. Morphine should not be given until operation has been offered and accepted by the patient. In recent postoperative cases the best approach is through the previous incision. If the previous abdominal wound is completely healed, the incision should be made about an inch to one side. The site of obstruction is usually felt without difficulty, and must be relieved. It is surprising how firmly organized adhesions may become in a very few days. The technic of freeing the obstructive condition must vary with the operative findings. Fiddle-string adhesions are cut and the points of attachment buried with a purse-string suture. Broad adhesions are divided with sharp dissection and an endeavor made to cover raw surfaces.

After obstruction of the small intestine has supervened for some hours it is our practice to insert into the dilated loop of jejunum a catheter which is carried out through the abdominal incision. Irrigations with normal salt can be accomplished through this channel. Although "milking out the dilated intestine" has been advised by many surgeons, we have felt that this

treatment involves too much manipulation for safety.

In obstructions of the large bowel drainage of the small intestine is also accomplished by jejunostomy. In cases of long standing obstruction with marked toxemia, where an attempt to free the obstructing adhesions seems hazardous on account of the condition of the patient, a jejunostomy should be performed through a small high left rectus incision. This procedure may carry a patient out of the acutely toxic period and allow the obstruction to be relieved with safety at a later date. It is frequently noted that after the small intestine has been drained, and the intra-abdominal pressure reduced, as by an ileostomy, jejunostomy, or cecostomy, an apparently complete bowel obstruction will allow fluid and gas to pass.

We consider that the treatment of the conditions discussed above is definite and positive. In abdominal distention (due to ileus or peritonitis) without obstruction, gastric lavage, compresses to the abdomen, colon irrigation and intravenous fluid medication are instituted. If from the increasing pressure, fluid keeps flowing into the stomach, and gastric lavage proves unsatisfactory, jejunostomy is indicated. If the stomach can be kept properly emptied, jejunostomy gives no added advantage. The stomach tube must be passed early.

In intestinal obstruction operation, with or without drainage of the intestine, is indicated as early as possible. Conservative treatment, "Waiting for a kink to unwind" is dangerous, and is usually based upon a lack of careful consideration of clinical symptoms.

The following cases typical of post-operative obstruction, developing soon after operation, have been selected as illustrations:

CASE 1. Operation, St. Luke's Hospital, January 19, 1924, cholecystectomy. Discharged from the hospital on February 2, 1924. Readmitted on February 15, with history of repeated vomiting, and evidence of first partial and

later complete upper intestinal obstruction. Operation February 16 showed duodenum closely adherent to the lower surface of the liver and the gall bladder fossa, which caused complete obstruction of the duodenum. This adhesion was not separated, but a posterior gastroenterostomy performed. Convalescence uneventful.

CASE 11. Patient aged sixty-nine. Operation St. Luke's Hospital November 1, 1927. Low midline incision. Very large multilocular cyst presented, partly aspirated and delivered with long pedicle arising from left broad ligament. This was tied off and raw surfaces covered. November 4 the abdomen was moderately distended with gas, but fecal matter was returned by colon irrigation. November 5 colon flushes returned practically clear; some gas was passing but very little. The distention was increasing. Patient was nauseated and vomited a small amount of mucus. One thousand c.c. 10 per cent glucose in saline intravenous administered. November 6, 2:30 A.M. patient was having cramp-like pains. Distension still present, and peristaltic waves were seen passing across the abdomen. Occasional gas bubbles passed through the funnel drip. Operation November 6, 1927, 10 A.M. through old abdominal incision. Intestines were greatly distended, both large and small, but free from evidence of peritonitis. Small amount of serosanguineous fluid in the belly. In the left broad ligament the sigmoid was attached with organizing adhesions through a distance of about $2\frac{1}{2}$ inches. When these adhesions were freed, sudden gurgling of gas was heard, indicating that the obstruction had been relieved. A catheter was sewn into a dilated loop of jejunum, drawn out through a gap in the omentum through the upper end of the wound, to make certain of upper intestinal drainage, should the sigmoid again close. Abdomen closed. During the next eight or nine days the patient continued to be moderately distended. Gas and fecal matter were passed. Intravenous injections of 1000 c.c. of 10 per cent glucose in saline were made twice daily for eight days, and once daily for the next seven days. Massive milk and molasses enemas were given frequently and produced the best results. This procedure is dirty but the most effective to iron out kinks and angles in lumen of the bowel. By the fourteenth day the patient was walking and left the hospital without

further complications on December 7. She has been entirely well since that time.

CASE III. Operation January 24, 1929. Dante Sanitarium, for two enormous fibroid tumors of the uterus and a cystic right ovary. Supravaginal hysterectomy and right salpingo-oophorectomy. Stump of cervix and right broad ligament peritonealized in the usual manner. Convalescence uneventful. Patient home on the 12th of February, 1929 (home 110 miles from this city). Returned to hospital on February 20 with a history of very severe abdominal pain, coming on suddenly on the evening of February 17. Patient vomited soon after onset of pain. Pain was paroxysmal in character, severe, had continued until her admission to the hospital. Her physician at her home told her she had a "kink which would straighten out." The vomiting became fecal and patient markedly toxic and dehydrated. When admitted to the hospital the patient was in marked acidosis, with deep stupor but could be aroused. Pulse of poor quality, about 100. Temperature subnormal. She was given 1000 c.c. of 10 per cent glucose in salt solution intravenously. Operation under ethylene anesthesia on February 20. Incision through dense clean scar of the old operation. Considerable clear, yellow fluid in the abdomen. Dense adhesions found binding the sigmoid over to the right of the cecum. The terminal ileum was angulated and obstructed in the right iliac fossa. After freeing this obstruction it was found that a small portion of the terminal ileum was bound down in the right iliac fossa by a congenital band of peritoneum which was separated with some difficulty. A catheter sewed in the jejunum was led out through the abdominal wound. Patient received a second glucose in salt intravenous infusion, but expired twelve hours later, a victim of delay and conservatism.

CASE IV. Patient was subjected to 2 cesarean operations. During the three or four years following the first cesarean operation the patient had frequent symptoms which were undoubtedly attacks of partial and almost

complete intestinal obstruction. These cleared. We were called upon to do a second cesarean operation, but at the time of this operation no exploration was made, since a long period of time had elapsed since the last attack of partial obstruction, and there seemed to be no indication for prolonging the cesarean operation by an abdominal exploration. Two or three days following the cesarean operation the patient developed complete obstruction of the small intestine. This condition called for another abdominal operation. On opening the abdomen it was found that the mesentery of the transverse colon was tightly adherent to the posterior parietal peritoneum and was pulled down before the ligament of Treitz, leaving a small ring through which more than half the small intestine had herniated. This hernia had never become completely occluded until the distention occurred, which followed the insult of the cesarean operation, with its associated postoperative ileus. At the time of operation this hernia was angulated sufficiently to completely block the bowel in this ring.

CASE V. Aged twenty-four. Operation St. Luke's Hospital March 13, 1930, for right ovarian cyst and chronic appendix. Low, mid-line incision. Right ovarian cyst and appendix removed in routine manner without difficulty. Abdomen closed. Convalescence entirely uneventful. Temperature normal. Pulse 80-90. Patient allowed up and around ward on the tenth day. On March 23 at 8:00 P.M. patient had sudden onset of excruciating pain in the right lower quadrant and vomited dinner eaten at 6:00 o'clock. Vomitus continued until operation at 10:00 P.M. Pains definitely paroxysmal and very severe. Abdomen sore between paroxysms which came every two or three minutes. Peristaltic waves seen. Operation March 23 at 10 P.M. through old incision. Two adhesions of the ileum found to the cecum, with a loop herniated through the space between these and also attached. These adhesions were very well organized and were freed with careful knife dissection. Raw surfaces peritonealized. Postoperative convalescence entirely uneventful.

ACUTE DILATATION OF THE STOMACH*

ROBERTSON WARD, M.D.

SAN FRANCISCO, CALIF.

ACUTE dilatation of the stomach, a rare primary lesion, is seen by far most commonly as a sequel to laparotomy. McIver¹ has shown experimentally that this phenomenon may take place at any time under general anesthesia where there is a possibility of the free passage of air through the esophageal orifice, and this is the probable explanation of its occurrence in the majority of cases where the site of operation is extra-abdominal.

The dilatation itself is of the nature of an acute paralysis of the gastric walls and, though occasionally limited to the stomach alone, it is more frequently accompanied by similar changes in the upper intestinal tract. Whether or not the primary paralysis was caused by air drawn into the stomach during anesthesia, the atonic viscus soon contains secreted, imbibed or regurgitated fluid. Probably the most common cause of the gastric paralysis is infectious material in the abdominal cavity and in these instances the duodenum and jejunum are invariably similarly involved. It will be found, moreover, that a varying degree of gastric dilatation is responsible for, or at least intimately associated with, the stormy convalescence seen, and often otherwise unexplained, in clean operations upon the lower abdominal structures or the bile passages.

In most instances, the diagnosis is not difficult. The blown-up, drum-like abdomen with visible or palpable tumor mass on the left side; the constant effort to bring up gas, sometimes in vain, sometimes with copious and recurrent eructations, often with foreboding hiccough, are signs which should lead any observer to a correct interpretation of the underlying condition. In its earlier stages the process is not so easily determined, as the stomach is not entirely lacking in tone and the most

common symptom is frequent effortless vomiting, usually of clear or slightly bile-stained fluid. If, at this time, proper treatment is instituted we shall seldom see the extreme condition first pictured. However, if the condition is allowed to progress, symptoms of toxic absorption from the paralysed stomach and duodenum overshadow those of mechanical origin, and the face rapidly becomes ashen or even cyanotic, the pulse becomes rapid, respirations are rapid and shallow, and shortly before, sometimes just after death, immense quantities of blackish-brown or dull greenish fluid flow from mouth and nostrils. The outflow, which gushes rather than is vomited, is caused by the gas associated with the condition and not by active contraction of the stomach musculature.

Acute dilatation of the stomach, looked upon with so much alarm by early writers, should no longer be counted as a possible cause of death. The suspicion that such a condition exists can be verified by the passing of a duodenal tube and treatment for its relief can be as simply carried out. Gastric dilatation cannot cause death unless, unsuspected, it remains untreated.

Having suspected its presence, a duodenal tube of the Levin² type may be slipped through the nostril and passed into the stomach without difficulty. If the tube has been well lubricated with petrolatum, jelly or glycerine, it is unnecessary to cocaine the nose or throat though this is sometimes advisable in a nervous or excitable patient. Five per cent cocaine on an applicator is the local anesthetic of choice. By the use of the tube described, the stomach may be kept continuously empty without the oft repeated, distressing gastric lavage through a large stomach tube. Moreover, there is ample evidence to show that the stomach once

* From the Department of Surgery, Univ. of California Medical School. Submitted for publication, April 15, 1930.

emptied by gastric lavage refills rapidly with regurgitated and secreted fluid unless a continuous mild suction is maintained.

FIG. 1. Apparatus for Continuous Gastric Drainage. D, Levin duodenal tube, No. 14 F., to be slipped through nostril. A, hemostat clamped on tube to lavage solution, L, which is changed to B only during lavage; C, drainage tube, the end of which must be kept submerged; S, Connell suction apparatus, the barrel of a triumph syringe fitted with two-holed rubber stopper. Constant dripping from container, E, regulated to about 100 drops per minute by petcock, P, causes a mild negative pressure due to air bubbles carried down the glass tube between drops of water.

For the application of this suction we have devised an apparatus as illustrated in the accompanying diagram (Fig. 1). This method^{3,4} has been used for more than five years in the Surgical and Gynecologic

Service of the University of California Hospital and we feel it has saved many lives. It has been used in paralytic ileus, which may or may not be due to peritonitis, in intestinal obstruction, in acute gastric dilatation and even in persistent postoperative vomiting not accompanied by dilatation or ileus. Its manifold advantages, pointed out by Brown^{5,6} are: (1) Relief from conditions caused by gas and regurgitated fluids is obtained. (2) There is either interrupted or continuous lavage of the stomach and, in some cases, of the duodenum. (3) Nausea and toxemia are relieved. (4) The patient may drink water freely, relieving that most distressing symptom, thirst. (5) Transgastric feeding and medication are made possible. (6) The patient is so much more comfortable that he often begs for the return of the duodenal tube after having once experienced the relief afforded by its use.

When gastric or duodenal drainage is prolonged, care must be taken to prevent alkalosis. Because of long continued drainage, large amounts of chlorides, secreted into the stomach as hydrochloric acid, are lost to the system and alkalosis results. These chlorides must be replaced by massive subcutaneous injections of normal saline solution. In this way the ominous drop in blood chlorides is prevented and the fluid balance of the body is maintained. Normal or 4 per cent sodium chloride solution should replace bicarbonate of soda solution for gastric lavage. Glucose should be administered intravenously for its nutrient value if food by mouth is withheld for long.

SUMMARY

Acute gastric dilatation, formerly considered a serious and frequently fatal complication, should no longer be a possible cause of death. Suspicion of its presence should lead to a speedy test by transnasal insertion of a duodenal tube. Treatment by the apparatus for continuous gastric drainage herein described is simple and rapidly efficacious.

PREOPERATIVE AND POSTOPERATIVE THERAPEUTIC USE OF DEXTROSE (GLUCOSE)*

PAUL TITUS, M.D., F.A.C.S.

PITTSBURGH, PA.

DEXTROSE or glucose as it is more commonly known, is one of the most important therapeutic agents developed within recent years. The underlying basis for its use is simplicity itself, because "in any diseased state nothing could be much more fundamental as supportive treatment than to supply a patient with food and water in such a form and by such a route that these are immediately available to the starved and thirsty tissues."¹

During the past five years or more much has been written about the surgical aspects of the use of dextrose. On reading over the literature one is struck immediately by the diversity of ideas expressed and opinions offered regarding certain essential matters such as indications, dosage, good and bad results, and whether or not insulin should be added, to say nothing of the general disregard of how very slowly intravenous injections of dextrose *must* be given in order to obtain full therapeutic effects and to avoid various undesirable consequences.

Probably this is due to the rapidity with which this old-new agent has sprung into its present prominence so that many of us using it still fail to appreciate that a dose of dextrose is a determinable matter definitely governed by rules of rational therapeutics. For example, a recent publication on the intravenous use of dextrose under certain conditions would be of inestimable value except that the author advises its injection by means of a modified blood transfusion outfit, apparently as rapidly as it can be pumped in. Such a method entirely disregards the consequent strain on the renal threshold, the wasteful spill of sugar through the urine, the hyper-

insulinism and reactions from overstimulation of the pancreas, possible overloading of the weakened heart muscle, as well as the incontrovertible fact that the therapeutic effect of the dextrose is dissipated and lost in direct ratio to the excessive rate of its injection (or faster than 0.8 gm. per kilo body weight per hour).² This same author would say nevertheless that he obtains good effects with his ways and of course some benefits are to be expected, but it may be pointed out that his results would be still better from the same dose properly given, the effects less erratic and uncertain, and the glucose reactions which he does not detail could be entirely avoided by the observance of a proper technic.

In this clinic as probably in many others the combination of obstetrics and gynecology in one service afforded an unusual opportunity for intimate contact and interest in the development of dextrose therapy as a standard treatment for the pregnancy toxemias, only to find suddenly that we had been carried along into an active application of this same agent to surgical gynecology. We use it preoperatively by mouth as a preventive of post-anesthetic nausea, vomiting and acidosis; each major operative case is routinely given at least one intravenous injection of hypertonic dextrose solution as an immediately postoperative procedure; we object, with valid reasons, to the addition of insulin for these non-diabetic patients since we believe that it is not more insulin to burn up available sugar which is required, but rather more sugar to be burned, whilst the patient is perfectly capable of forming in her own pancreas all and more than all the insulin she

*From the Department of Obstetrics and Gynecology, St. Margaret Memorial Hospital, Pittsburgh. The technical phases of this work were conducted under the generous provisions of the John C. Oliver Memorial Research Foundation at the St. Margaret Memorial Hospital. Submitted for publication April 28, 1930.

needs; we regulate our dextrose dosage and rate of administration; and we do not have reactions.

It is similarly used in other divisions of this hospital and our services are notably free from such postoperative complications as even ordinary vomiting, acidosis and shock. Moreover, patients thus treated react from the operation more favorably and promptly, do not complain of thirst or nausea, and actually seem to regain even their intestinal peristaltic tone more promptly than in former days.

GENERAL CONSIDERATION OF DEXTROSE THERAPY

A knowledge of certain fundamental facts regarding dextrose metabolism and dextrose therapy is essential in order to obtain uniform results from its use. These can best be discussed in a briefly tabulated form:

Dextrose and Glucose: Originally the word glucose was synonymous in a chemical sense with dextrose. Practically, however, there was a great difference because then, as now, glucose was prepared on a large scale for commercial purposes. Glucose sold as such over the druggist's counter still contains various impurities, and reactions and even deaths have followed its intravenous use.

It was on this account that in the Tenth Revision of the U. S. Pharmacopeia in 1926 need was realized for the establishment of certain fixed standards. At this time the term *dextrose* was officially adopted and listed for that sugar so prepared and purified that it could be used for all therapeutic purposes.

The medical use of the term glucose is no longer correct, therefore, because glucose is the impure commercial sugar or syrup, and one should speak now only of dextrose in referring to the medicinal agent which has so commonly been called glucose.

For intravenous use chemically pure dextrose is no longer necessary if "dextrose, U. S. P. X." is specified.

Reactions following the intravenous use of dextrose solution are unnecessary and avoidable³ providing no technical errors are allowed in its preparation or its administration. Safe solutions are easily prepared in any hospital, or recourse may be had to one of the many hermetically sealed ampules of dextrose solution now on the market providing they contain no cresol as a preservative. These may be employed without risk of reactions unless the operator fails to use freshly distilled and immediately sterilized water in their dilution, or else gives the solution too rapidly, or too cold, or in overdose.^{1,4}

Modes of Administration: Dextrose in solution may be given by mouth, by rectum, subcutaneously or intravenously.

The first two routes probably require little or no comment but certain points common to the latter two need some clarification.

Dextrose solution in itself is not especially irritating when given subcutaneously regardless of its concentration, and when sloughs occur as they occasionally do these are probably the result of pressure necrosis from having been injected too rapidly.

These necrotic sloughs were more common formerly, before the days of intravenous injection, when submammary infusion was the only substantial route of extraoral administration. One probable cause has been alluded to, but it will be remembered that "glucose and soda" was a favorite combination in solution. Bollman⁵ has pointed out that alkalis cause a rapid disintegration of glucose or dextrose when heated, so that they should never be added to the sugar solution before sterilization. This and the chemical degeneration of sodium bicarbonate into the more caustic sodium carbonate under sterilization are probably additional factors in the causation of these sloughs.

In any event it is apparent from the foregoing that sodium bicarbonate has no place in combination with dextrose solutions for intravenous injection, and in

fact also should not be used for subcutaneous infusion if such a method of administration of dextrose must be employed.

By the intravenous route underdosage and over-rapid injection are grievously common faults. The consequences of the latter have already been alluded to in an earlier paragraph.

Regarding dosage careful investigations¹ have disclosed that a single therapeutic dose of dextrose for an average sized adult is approximately 75 gm. The maximum rate at which this should be given is 0.8 gm. per kilo body weight per hour² in order to have it completely utilized by the body. Translated this means that such an injection of an average therapeutic dose to an average sized adult requires approximately one hundred minutes or *one and three-quarter hours!*

More than this amount at this maximum rate is likely to overstimulate the pancreas in its insulin-producing capacity resulting in an endogenous hyperinsulinism accompanied by hypoglycemia and actual reactions from this source. The same ill result is to be expected even more constantly from the intravenous drip of Matas⁶ or venoclysis as it is called by Hendon⁷ unless the rate of injection is reduced in these prolonged injections to about one-third that speed at which single therapeutic doses can be given. Hendon even reduces his dosage to one drop per patient's pulse beat.

The fallacy of adding insulin to such injections of dextrose in these normal non-diabetic individuals is emphasized by these important facts.

The strength of the dextrose solution to be chosen depends on various factors such as the condition of the myocardium, the degree of dehydration, acidosis, etc. My own preference for single doses is 300 c.c. of 25 per cent solution, since the effects of the hypertonic solutions seem more prompt and more pronounced. A 15 or 10 per cent solution may be used (500 to 750 c.c. respectively) if more water is required.

For prolonged venoclysis the solution should not be stronger than 5 per cent but this injection may be continued even for days if, as said before, the rate of injection is reduced to one-third the maximum of the Woodyatt and the Wilder and Sansum formula or, not more than 5 or 6 c.c. per minute. Gallie and Harris⁸ say that they prefer salt solution for this purpose because dextrose solutions may result in thrombosis of the veins if the injection is prolonged. My own belief is that this objection is largely theoretical while the therapeutic value of the dextrose is greatly superior to that of salt; moreover such injections have been employed in our hospital a vast number of times without any such difficulty.

It is also essential in the prevention of reactions to maintain heat in the solutions during their injection. The administration of cold solutions is probably a frequent cause of reactions.

INDICATIONS FOR DEXTROSE ADMINISTRATION

PREOPERATIVE: In all elective operations the patient should be directed to increase the carbohydrates in his food for a period of several days before his operation. Well sweetened orange juice, or other fruit juices with cane sugar or powdered dextrose should be freely drunk; honey may be eaten with meals; light desserts including ice creams and fruit ices are advisable, and clear hard candy (no chocolates or bonbons) may be eaten after meals.

The patient's carbohydrate reserves will thus be built up in advance; the anesthetic will be less toxic, and postanesthetic nausea and vomiting will be materially lessened by this preliminary preparation.

In such surgical emergencies as traumatic shock, intestinal obstruction, or prolonged preoperative infection as from prostatitis or certain cases of cholecystitis, an intravenous injection of dextrose solution with or without the addition of sodium chloride (depending on the presence or absence of vomiting with loss of chlorides)

should be given while getting ready for operation. In these instances the injection should preferably be made of one of the weaker solutions given fairly rapidly. This supplies the necessary volume of fluid but still need not exceed the formula of Woodyatt, and Wilder and Sansum for the introduction of the sugar.

Many a bad operative risk can be turned into a fairly safe surgical venture by a judicious period of preoperative preparation in which dextrose injections properly chosen and properly carried out play an important rôle.

POSTOPERATIVE: Postoperative indications for intravenous dextrose administration are three fold: (1) Routine supportive treatment as a restorative measure, or as preventive or active treatment of vomiting and (2) preventive, or active treatment of shock. These are immediate postoperative indications, whereas there is a third group having slightly more remote relationship to the operation. In those cases (3) where peritonitis is a complication as following a ruptured appendix, or peritonitis with profound toxemia as with intestinal obstruction this treatment gives some of the most spectacular results which are to be seen in any class of cases. Post-anesthetic pneumonia⁹ as well as acute nephritis with urinary suppression also fall into this third group.

Probably the simplest way of considering these conditions and their treatment in detail is to outline them in tabulated form as follows:

Group I. Routine Postoperative Injection as a Restorative, and as a Preventive or Active Treatment of Vomiting and Acidosis:

1. As routine postoperative measure; 300 c.c. of 25 per cent dextrose solution injected intravenously at 3 c.c. per minute. Repeat once or twice if necessary at four to six hour intervals.

2. This is also preventive treatment of postoperative vomiting.

3. If treatment is instituted promptly the same procedure outlined for routine

injection should be vigorously pushed for postoperative nausea and vomiting. If vomiting has been excessive before treatment is begun add to solution 1 to 2 per cent sodium chloride to compensate for loss of chlorides in emesis.

4. Proctoclysis of 10 per cent dextrose or of tap water by Harris tidal-stand method is preferable to the Murphy drip.

Group II. Preventive or Active Treatment of Shock:

1. After prolonged operation give 400 c.c. 20 per cent solution of dextrose intravenously at 4 c.c. per minute, with intrarectal injection of one pint of hot dextrose (10 per cent) with sodium chloride (2 per cent). Repeat intravenous injection once or twice at from four to six hour intervals if necessary.

2. Active treatment of postoperative shock; 750 c.c. of 10 per cent dextrose solution intravenously at 7.5 c.c. per minute, or if more haste is necessary 750 to 1000 c.c. of 5 per cent dextrose solution with 1 per cent sodium chloride at 15 c.c. per minute; or 500 c.c. gum acacia and dextrose solution at about the same rate.

Valuable time should not be wasted on attempts at venopuncture. The veins are frequently so collapsed as to be difficult of access by needle and should be cut down upon without delay. The observance of the technic of Larkin,¹⁰ of lifting a triangular flap in the vein, and then closing the wound with an encircling suture tied in a bow-knot after the injection is ended makes it possible to use this same vein anumber of times for subsequent injections if necessary.

Group III. Suspected or Actual Peritonitis, Intestinal Atony or Beginning Ileus, and Toxemia Following Intestinal Obstruction.

1. With suspected or local peritonitis give 300 c.c. of 25 per cent dextrose solution intravenously at 3 c.c. per minute repeated after four to six hours for day or two. With general peritonitis of mild degree this same procedure will be sufficient, and this is also true of intestinal atony or beginning ileus.

2. If these conditions have existed for some time or are of serious degree and do not respond quickly and sufficiently, change to prolonged intravenous administration (venoclysis) giving 5 per cent dextrose solution through tied-in cannula at about 5 c.c. per minute. Continue this over period of several days without interruption. In cases of marked peritonitis where vomiting has been severe, and especially after operation for intestinal obstruction from 1 to 3 per cent sodium chloride should be added, until blood chlorides are restored to normal.

3. Following operations for intestinal obstruction venoclysis of 5 per cent dextrose solution with or without 1 to 3 per cent sodium chloride is not merely recommended but urged as a routine procedure. This should be continued as long as five or six days if necessary.

It is, of course, understood that the foregoing is merely an important addition to other rational methods of treatment already established, and it is probably unnecessary to point out that there are many other surgical indications for the use of dextrose, particularly by the intravenous route. The occasions for its use will constantly suggest themselves to the surgeon who keeps in mind the fact that food and drink are essential to any individual, and that to furnish such elemental but

necessary support to a patient who is seriously sick may frequently be the determining factor between his recovery and his death.

SUMMARY

1. The preoperative and postoperative administration of dextrose (D glucose) is now regarded as of great importance in the general care of the surgical patient. Intravenously injected dextrose will frequently convert the bad surgical risk into a comparatively safe surgical venture.

2. Administered preoperatively by mouth or by vein as necessity may require it acts as a preventive of postanesthetic nausea, vomiting and acidosis.

3. Routine postoperative intravenous injection of hypertonic dextrose solution is recommended in the prevention of vomiting, acidosis and shock, intestinal atony, etc.

4. Dextrose solution injected intravenously is effective supportive treatment for traumatic shock, peritonitis and the toxemia of intestinal obstruction.

5. Modes of administration, dosage and indications for dextrose therapy are discussed in this paper.

6. The assertion is again made that unfavorable reactions from intravenous injections of dextrose are avoidable if certain technical but simple essentials are understood and observed by the operator.

POSTOPERATIVE SALIVARY GLAND INFECTIONS*

FRANK D. JENNINGS, M.D.

BROOKLYN, N. Y.

AMONG the complications which may ensue after surgical endeavor, acute salivary gland infections rank low in incidence but high in actual and potential danger. Whether or not its occurrence is an indication of low resistance, whatever its etiology may be, its significance is always sinister.

Much has been written on this topic, notably the parotid gland involvement, because it is the most common, far exceeding submaxillary and sublingual in frequency. A review of the literature by the writer in 1923, disclosed contributions by surgeons of many countries, from Paget in the eighties of the last century down to our time. These surveys indicated no unanimity of opinion as to etiology, but did point out its seriousness, all concurring that the average mortality was about 30 per cent. The accurate computation of mortality is difficult, because the condition so frequently manifests itself as a complicating factor in a patient already gravely sick.

The literature since 1923 has been similarly reviewed. A number of writers have contributed scholarly studies of this most distressing lesion. They, however, have shed no light on the causative factor. Speculation continues as to whether it is hematogenous, ascending (via salivary ducts), traumatic (by anesthetist), or lymphatic. The preponderance of evidence leans to the first two. It is pointed out that trauma in general, in industry, in boxing and other rough sports, is not followed by parotitis. As for lymphatic approach, the parotid lymph nodes derive lymph only from the gland itself, the external ear and eyelids, which makes it doubtful that the infection reaches the gland through lymphatic channels.

There is much evidence to support

both the hematogenous and ascending etiologic concepts and it may well be in many instances that a combination of both factors enters into its genesis. The adherents of the ascending or ductal theory base their arguments on a dry mouth, salivary stasis and the fact that cultures from the gland, Stenson's duct and the mouth are identical in postoperative parotitis. Complementing this is the observation that the inflammatory process begins in the center of each lobule. Resemblance to ascending biliary, urological and mammary infections is also advanced in support of this theory.

However, postoperative patients generally suffer from dry mouths and some degree of salivary stasis, if not oral sepsis. If these factors are potent, salivary infections should be more frequent. The fact that the invasion is so generally of the parotids is explained on the hypothesis that saliva produced by the sublingual and submaxillary glands is more bactericidal than that of the parotid and also that the ducts of the former open under and are kept clean by movements of the tongue. Stenson's duct opens outside the alveolar process, near the molar teeth, which are frequently carious.

The rapid onset after operation, the extent of the involvement and the associated septic symptoms, on the other hand, point to a hematogenous source, entirely apart from those instances, in which the occurrence is manifestly pyemic.

The diagnosis offers no difficulty as a rule. A tense, tender swelling develops in front of either ear. The skin is red. The swelling is painful. There is a rise in temperature, with associated prostration and discomfort. Such is the familiar picture of acute parotitis.

It may slowly subside on the involved

side as it appears on the opposite side. The latter may quiet down and the original side again become active. Suppuration may or may not occur. If it does, spontaneous drainage may eventuate through the external auditory canal, the temporal fossa or the pharynx.

Prophylactic treatment emphasizes the

necessity of adequate oral hygiene before and immediately after operation. Careful cleansing of the mouth, keeping the oral mucosa as moist as possible, postponing elective operation in the presence of bad oral hygiene are all important.

Once it develops, iodine and ice locally are useful, chewing gum or acidulous

lozenges (lime or lemon) are helpful in stimulating a flow of saliva. The free intake of fluids is essential and in the bad cases, hypodermoclysis is beneficial.

If pus forms, obviously drainage is necessary. Incision may be made at the level of the angle of the inferior maxilla, keeping in mind the location of the facial nerve. It should preferably be horizontal and once the dense sheath is opened, the gland proper may be entered with a blunt forceps.

Fisher,¹ in a recent study, advocates the daily intravenous use of 5 per cent mercurochrome. He considers it effective, especially in those infections due to staphylococci, often aborting a diffuse, destructive process. He also, when drainage is needed,

describes a Y shaped incision, one arm of which begins at the zygoma, the other at the mastoid, both joining below the angle of the jaw to continue down to the supraclavicular notch. The writer has had no experience with either, but believes they have merit.

A review of the records at St. Catherine's Hospital, for the past five years, discloses 13 cases with 7 deaths. Further analysis of the record removes 4 of the deaths for the reason that the parotitis was not a determining factor. In 1, the parotid infection subsided eighteen days before death, 2 had secondary wound hemorrhages and 1 died of embolism. The mortality in this group, as accurately as it can be estimated, is therefore about 24 per cent.

SUCCESSFUL MOUTH TO MOUTH INSUFFLATION IN THE ASPHYXIATED ADULT

A NEW METHOD*

PALUEL J. FLAGG, M.D.

NEW YORK

THERE is probably no emergency in operative work which is so demoralizing and fatal as acute asphyxia. The picture of the patient whose respirations are completely obstructed, who passes rapidly from cyanosis to lividity, dilated pupils, and finally, through muscle spasm to the complete relaxation of the antemortem state, is one which we can never forget.

In the face of this condition, what do we ordinarily do to meet it? Put a mouth gag between the teeth, pull out the tongue, do Sylvester artificial respiration, dilate the sphincter, give hypodermic injections, and make other gestures, usually without any result.

In a previous communication,¹ the writer has met this condition by laryngoscopy, suction, intubation and insufflation of oxygen CO_2 . This method, which is growing in popularity in the resuscitation of the newborn, has also been found valuable in the adult.

The insufflation of oxygen and CO_2 is of the greatest possible value after laryngoscopy and intubation. Facilities for intubation should always be available for use. A description of the author's pocket flashlight laryngoscope has previously been published² and the intratracheal tube employed has been described.³ In the intervening three years, the writer has come to the conclusion that this equipment is as essential as the anesthetic agent. Its construction is so simple that it does not get out of order.

The following recent case illustrates the extreme value of immediate laryngoscopy and intubation in asphyxia, due to obstruction.

¹ FLAGG, P. J. Treatment of asphyxia in the new-born. *J. A. M. A.*, 91: 788, 1928.

³ FLAGG, P. J. Intratracheal inhalation. *Arch. Otolaryng.*, 5: 394, 1927.

Patient, male, twelve years old. Manhattan Eye & Ear Hospital, N. Y. February 18, 1930.

Temperature: 105.6°F. Rather fat, with thick-set, short neck; previously anesthetized on February 9, 1930. The anesthesia at this operation was characterized by extremely rapid respiration, requiring a high percentage of oxygen to prevent cyanosis; air was given frequently without effect, in the hope of reducing the respiratory rate. Recovery had been prompt, without complication.

This anesthesia, the second, took place on February 18, 1930; gas oxygen without ether operation for jugular resection. The characteristic rapid respiration developed within a few minutes with a rate of between 50 or 60 a minute. It was impossible to bring down these respirations by the addition of oxygen or air. The jugular wound had been closed, attention was being directed to the mastoid wound; severe bleeding from sinus had just been controlled. A new incision was made posteriorly. At this time, the patient's respiration seemed to become obstructed as well as rapid; no pharyngeal tube had been used because of the extremely light anesthesia maintained; his color was cyanotic, and oxygen did not relieve the cyanosis. The neck seemed to be swollen and full. Removing the mask, I found the lower lip caught between the teeth which were tightly clenched. The cyanosis increased in spite of oxygen being offered to the patient. Anticipating an accident, I called for suction and my laryngoscopic apparatus. The draperies were thrown from the face; the lips were livid. The respiratory effort became weaker and weaker, and finally ceased. The pupils dilated and the clenched teeth relaxed. The small laryngoscope was introduced without difficulty. The soft parts of the airway were deep blue and completely relaxed. A quantity of mucus in the hypopharynx was removed and the glottis located. During this time, the surgeon was compressing the chest, but there was no exchange of air and no respiratory movement. The No. 7 intratracheal tube employed for anesthesia was intubated. There was slight tone of the cords which were closed, but there were no active reflexes and no spasm.

* Submitted for publication, March 6, 1930.

I immediately blew forcefully into the tube, distending the patient's chest. At the crest of the insufflation, a convulsive inspiratory effort

The cause of this respiratory failure is thought to be due to continued anoxemia from nitrous oxide and oxygen (this

FIG. 1. Author's laryngoscope showing large, medium and baby specula.

of the patient's chest took place, as if to deepen the effects of my insufflation. Allowing the expiration to escape through the tube, I blew in again. The color improved at once; oxygen was then blown into the tube; the patient seemed about to breathe spontaneously, then did breathe through the tube. I insufflated once more, the patient's respiratory effort complementing my insufflation. The color became brilliant, a sharp laryngeal spasm developed from the presence of the intratracheal tube which was immediately extubated. The patient breathed deeply and forcefully and made convulsive movements of the face and body (anoxic jactitation in reverse order). The patient was then given a pharyngeal tube and pure oxygen with a little ether. The respiration slowed down, ether was stopped, and gas oxygen continued, the patient recovering consciousness on the table.

FIG. 2. A, No. 9 intratracheal inhalation tube. B, No. 7 intratracheal inhalation tube. C, No. 5 intratracheal inhalation tube covered with Penrose tubing. D, Penrose tubing. E, Obturator. F, Naked tube with obturator removed. G, Suction catheter of rubber. H, Intratracheal suction tube.

anesthetic having been chosen because of the fact that the patient had an acute nephritis and bronchitis), resulting in complete anoxemia through muscle spasm. The sequence of anoxemia, spasm, cyanosis, relaxation of the masseters and the glottis, dilated pupils, absence of respiratory effort and ineffectual artificial respiration by direct compression would certainly have resulted in death.

The curious phenomena of an inspiratory effort on the patient's part, at the crest of my direct mouth insufflation, rapid oxygenation, forceful expirations, rapid return of laryngeal reflexes upon oxygenation, within 6 or 8 breaths, and anoxic convulsions during recovery, all tend to confirm the condition as due to oxygen deprivation.

This patient's life was undoubtedly saved by prompt laryngoscopy, intubation and mouth insufflation.

POSTOPERATIVE KIDNEY COMPLICATIONS*

PROF. DR. OSWALD SCHWARZ

VIENNA, AUSTRIA

KIDNEY complications are among the relatively rare but clinically very important sequelae of operations. The following 4 basic forms may be differentiated: (1) Disturbances in the function of the kidney, (2) inflammatory, non-infectious diseases, (3) infectious diseases of the kidney, and (4) the effects of changes in the efferent urinary passages upon the kidney.

Postoperative disturbances of the function of the kidney, which in the majority of the cases are transient but, under certain conditions, may also lead to the death of the patient, may be produced by inhibitory reflexes which originate in the other kidney or in the bladder, when these organs are operated upon. Under such conditions there results either a reflex angiospasm, or a sudden overloading of function through the removal of the relatively still well-functioning sister organ (tuberculosis, hypernephroma), or, finally, the various non-specific insults, which the operation as such exerts upon the organism. The importance of this latter factor, German surgery has learned to appreciate more and more, since it has been shown that some of the cases of postoperative fatality, which are usually attributed to the shock of the operation, are merely masked uremias; for this reason a kidney function test is always done before every major operation, especially laparotomy, in many of the surgical clinics.

Postoperative, inflammatory, non-infectious diseases of the kidney in the form of simple degeneration, nephrosis, or even nephritis are usually attributed to the anesthesia, but in general it may be said that the effect of the anesthesia, especially since chloroform is no longer being used, is markedly overestimated. Braun (Zwickau), who deserves the greatest credit for the introduction of local anesthesia into Ger-

many, repeatedly emphasizes the fact that operations on the kidneys are the very operative procedures that are best done under general anesthesia. It is certainly correct, that entirely intact organs are no longer subjected to the previously mentioned reflex as well as anesthetic injuries, but it must be emphasized repeatedly, that even predispositions are sufficient in this respect, which we cannot discover even with our best functional tests and methods of examination. A certain factor of danger, which cannot be relieved at the time, is inherent in every one of these operations.

The infectious diseases of the kidney, owing to the very frequency of their occurrence, demand by far the greatest amount of consideration. Inasmuch as one of the most important prerequisites of their occurrence are postoperative changes in the efferent urinary passages, particularly in the pelvis of the kidney and ureter, these two latter conditions in this classification may be discussed together.

In the first place, a few remarks on the pathologic-anatomic fundamental principles. There can no longer be any doubt today, that the entire urinary tract reacts to the most varying insults, particularly also to infections, as a unit. This means that urethritis, cystitis, ureteritis, pyelitis, pyelonephritis, abscess of the kidney and pyonephrosis, are merely different localizations, and under certain conditions, different stages of the same disease process. One sees sufficient cases in which the entire urinary tract is actually attacked by the infection. But in contradistinction to such a unitary conception one must not overlook the fact in other cases the localization of the infectious process in a single section of the urinary tract is so predominant, that the conception of the previously mentioned disease pictures as more or less

* Submitted for publication, May 13, 1930.

isolated phenomena is absolutely correct. Inasmuch as the nomenclature in this field is by no means uniform, as a result of which there are basic difficulties in diagnosis, a few definitions of the terms used by us are in place. Under the term "pyelitis," we understand an inflammation of the mucous membrane of the undilated pelvis of the kidney; but if, on the other hand, the pelvis of the kidney is dilated, we speak of an "infected pyelectasis or hydronephrosis." Whereas the simple form of pyelitis always results from an ascent of the infection from the lower urinary passages, hydronephrotic infection may also arise in a metastatic way. A "pyelonephritis" is understood to be a suppurative inflammation of the interstitial tissue of the kidney, whereas the true parenchyma of the kidney is affected only secondarily in the advanced stages. In the fully developed cases one sees infiltrations of leukocytes in the transverse section of the kidney, which pass in the form of stripes along the urinary canaliculi from the cortex to the tips of the pyramids. Abscess formation may occur in any part of this course, most frequently at the surface of the kidney. This disease picture may be ascending, that is, reach the kidney itself from the pelvis of the kidney through an ascending infection, or a descending infection, in which case a metastatic cortical abscess forms at first from bacterial emboli in a glomerulus, from which the infection of the medullary substance of the kidney ensues. In the individual case a differentiation between these two modes of infection is hardly possible.

Formerly the colon bacillus was almost exclusively (up to 90 per cent of the cases) blamed as the exciting germ, but more recent investigations have shown that cocci of a great many types are constantly gaining greater importance (up to 40 per cent of cases) in the hematogenic infections and, particularly, in the sequelae of operative interventions, in which we are especially interested at this moment. In

this connection, brief mention is made of the fact that very recently the pathogenicity of the colon bacilli has again been questioned, a view that had previously been presented by Rovsing in 1898, but which had to be considerably modified later.

As is well known, predisposing factors also are always necessary for the occurrence of any infection. In the case of the occurrence of true renal infections, pyelonephritis and abscess of the kidney, these are practically unknown. *The indispensable prerequisite for an infection of the pelvis of the kidney, however, is a motor insufficiency with or without dilatation of the calyx-renal-ureter tube.* To speak more accurately, one would say: a prerequisite for a long-continued infection, as the acute infections of the mucous membrane of the renal pelvis, like every other superficial infection of a mucous membrane, shows a marked tendency toward a spontaneous recovery. A chronic suppuration originating from the renal pelvis, therefore, results only when this spontaneous recovery is prevented by complicating factors, and this happens almost exclusively as a result of a motor insufficiency of the efferent urinary passages and the backward stasis of the urine associated with it. *From this is drawn the clinically exceedingly important conclusion, that the diagnosis of "chronic pyelitis" as an independent disease picture is always a wrong diagnosis!* The chronic suppuration originating in the pelvis of the kidney is never an independent disease, but always merely a symptom, and the aim of the diagnosis is to determine what the factors are that prevent this tendency to spontaneous healing of the inflammation and favor the chronicity of the suppuration. Two pathologic factors enter into the discussion at this point, namely, the dilatations of the renal pelvis mentioned and the infection of the renal tissue itself.

According to the most recent status of investigations, I would like to differentiate 3 types of dilatations of the efferent urinary passages: (1) *congenital atony*, in which

group belong the frequently very large dilatations of the bladder, ureter and renal pelvis in the newborn, but even the hydronephrosis in movable kidneys is, in most of the cases, not a result of the renal dystopy but a phenomenon coördinated with it as a common expression of a universal hypotonia of the entire connective tissue apparatus; (2) *the mechanical dilatation* from peripheral obstruction of urinary outflow, and (3) *the adaptive relaxation*, by which term is to be understood the fact, that with moderate obstruction to the urinary outflow the renal pelvis and ureter reduce the tonus of their walls in adaptation to the changed dynamic conditions and consequently increase their capacity, without the wall being mechanically dilated or even overdistended. This is a very general compensatory mechanism, which we also see in other hollow viscera, for example, in the bladder with hypertrophy of the prostate, in the left heart with aortic stenosis, in the pulmonary alveoli with bronchial spasms, and numerous other conditions.¹ The functional character of these dilatations of the renal pelvis and the ureter and their difference from the definitive atony and dilatation is shown by the fact, that they may retrogress completely and permanently with suitable drainage therapy. The knowledge of this mechanism is of fundamental importance especially in the understanding and the treatment of the pyelitis of pregnancy and of the puerperium. Regardless of the type that has caused the accumulation of residual urine in the pelvis of the kidney, so long as it is present, it presents an absolute hindrance to the cure of the infection, and the first endeavor of every form of therapy consists in relieving the renal pelvis by intermittent or continuous drainage.

An infected residual urine in the pelvis of the kidney, therefore, is the primary cause of the chronicity of a renal pyuria; the second, as has been mentioned, is the

pyelonephritis. Whether there is such a condition as an uncomplicated pyelitis, that is, whether or not every infection of the renal pelvis is associated with a more or less extensive infection of the adjacent urinary canaliculi, is an important theoretical question; clinically, both of these conditions, pyelitis and pyelonephritis, can and must be sharply differentiated. In fact, we speak of a clinically important pyelonephritis when the kidney function shows only an indication of diminished function.

The diagnostic procedure in a chronic renal pyuria is, therefore, the following: In the first place, one should determine, with ureteral catheterization and possibly with the aid of pyelography, whether or not there is any residual urine in the pelvis of the kidney. If this is not the case, the chronicity of the pyuria can be due only to a pyelonephritis. In order to confirm this or in order to determine the extent of the destruction of the renal parenchyma, the simplest functional test with indigo carmine or phenolsulphonephthalein is sufficient. A further important differentiation of these two disease conditions is furnished by the clinical symptoms. Without going into any further detail, an almost universally made mistake should be corrected at this time: Pyelitis is never the cause of very severe pains or very high temperatures or even of a chill. *Every urologic disease having its onset with severe clinical symptoms, including high temperatures and chill, is due to either a metastatic infection of a previously formed hydronephrosis or, in the vast majority of cases, to the development of a metastatic cortical abscess in the kidney.* Inasmuch as the infections of the kidney following surgical intervention are almost always of hematogenic-metastatic nature, one may say, *that the embolic pyelonephritis represents the typical postoperative complication as far as the kidneys are concerned.* The sources of the infection are: the infected urinary bladder, from which the kidney may be infected both by an ascending and a

¹ Cf. SCHWARZ, O. Pathologische Physiologie der Harnblase. In: Handbuch der Urologie. Berlin, Springer.

metastatic route; every pus focus anywhere in the body; and, finally, the intestinal tract.

When we enter upon the discussion of the special pathology of postoperative infectious complications of the kidney, the term "surgical intervention" should be used in the widest possible sense. The simplest, but at the same time perhaps one of the most important of these surgical interventions is catheterization or the introduction of instruments into the urethra and bladder. It is a well-known fact that occasionally these procedures are followed by a chill even with a definitely aseptic procedure. *The cause of this so-called "catheter fever" is always a peracute sepsis, which leads to abscess formation, in rare cases in the prostate, but usually in the cortex of the kidney.* This phenomenon is interesting evidence for the teaching, particularly advanced by the Mayo school, of the organ specificity of germs, in which the germs originating in the lower urinary tract and brought into the blood circulation through the catheterization that slightly injures the mucous membrane of the urethra repeatedly and electively settle in the parenchymatous portions of the urinary tract. Thus, we believe today that with our advanced asepsis such infections are no longer produced by alien bacteria, but by a squeezing of the normal saprophytes of the urethra into the blood circulation, so that in these cases the germs are such as are specifically adapted to the tissue of the urinary tract. The existence of these metastatic cortical abscesses has been proved both clinically and by autopsies, as such catheter infections are usually only transient, but occasionally still lead to chronic or even lethal so-called uroseptic diseases.

It is well known how dangerous the first catheterization of a bladder with much residual urine is. When, in such a case, an infection results, under certain conditions a fulminating sepsis with a rapidly fatal outcome is associated with this apparently very harmless intervention.

Usually, however, these infections run a milder course and there results a gradually ascending infection from the bladder to the higher sections of the urinary tract. This, however, never remains confined to the pelvis of the kidney, but always sooner or later attacks the parenchyma of the kidney; there results a pyelonephritis with more or less marked diminution of the renal function and chronic urosepsis. One can almost say, that the purpose of an early prostatectomy is to anticipate these severe complications of the later stages. This ascent of the infection from the bladder to the higher sections is a much discussed but still not entirely solved problem. Aside from the fact that a route of infection via the lymphatics of the ureter has been proved, we know that the prerequisite for such an ascent is an insufficiency of the ureteral musculature including the occlusive mechanism of the ureter, so that the so-called vesiculoureteral reflux occurs. We can well understand that anatomic changes of the ureteral ostium, such as are produced by tuberculosis, spinal disorders, ulcerative cystitis, operative cicatricial distortion and injuries following the passage of stones, lead to a gaping of the ureteral openings. But we are not interested here so much in these conditions, but rather in those cases in which with an anatomically intact ureteral wall the ureter loses its tonus temporarily or permanently. This occurs under anesthesia with the use of local anesthesia of the bladder mucosa with very mild infection and similar harmless conditions, so that even with a slight increase of the intravesical pressure a reflux of the urine as far up as the pelvis of the kidney occurs. The cystographic evidence of these conditions is always easily obtainable. Personally I believe that this phenomenon depends upon a constitutional weakness of the musculature of the ureter and represents the slightest grade of the previously mentioned congenital atony.

We now come to the discussion of the

pathology of the ureter, which represents a very frequent postoperative complication of many types of operations. Gynecological operations, particularly, lead to injuries of the ureter, which almost invariably cause infections of the kidney. Special attention should be called to the fact that these infections of the kidney rob the immediate surgical successful transplantations of the ureters of their permanent results, as these transplantations, even when done with the most perfect technic, can neither replace nor simulate the natural occlusive mechanism of the ureter, so that there results either a wide communication or, more often, there results a stenosis at the site of implantation from secondary cicatricial contraction with subsequent dilatation of the efferent urinary passages, urinary stasis, infection and, finally, destruction of the kidney. Occasional permanent results of such transplantations cannot disprove the knowledge of the best German gynecologists obtained from extensive statistical experience.

Among the postoperative infectious complications in the kidney, all the different operations on the pus foci in the body assume an important position. After Rovsing in 1889 and later German authors, especially, Scheidemantel in 1913, called attention to the significance of tonsillitis, it is to the special credit of Rosenow, Bumpus and Meisser that they emphasized the connection between disease of the tonsils and infection of the kidney and that they considerably extended the discovery of the organ specificity of the bacteria. Here, where the postoperative connections interest us chiefly, attention must be called to the fact that such infections of the kidney result not very rarely during the operation on these pus foci, either because a protective pyogenetic membrane is ruptured by the operation (especially with osteomyelitis), or the bacteria are squeezed into the opened lymph spaces, as happens particularly with tonsillectomy by squeezing and pres-

sure. A not so very inconsiderable number of the acute septic fatalities after such operations have a peracute hematogenic diffuse pyelonephritis as an anatomic substrate.

Finally, the intestine is of the greatest practical importance as a source of the development of infections of the kidney. And as evidence of the importance that we attach to these factors, it should be said from the very beginning that the relative frequency of infections of the kidney in women should not be attributed to the short length of the female urethra, but rather to the relative frequency of the disturbances of motility of the intestines in females. The reports in the literature on the connections observed between infection of the kidney and disturbances in the activity of the gut (especially obstipation) vary considerably. A probable explanation for these differences of opinion might be the following: here, exactly as in the pelvis of the kidney, even a diminution of the motility with such a slight functional disturbance that it is not recognized by the patient, is sufficient and therefore escapes a superficial examination on the part of the physician. Colitis, appendicitis, cholecystitis, and even slight gastrointestinal disturbances lead to obstinate infections of the kidney in spite of all forms of therapy, which rapidly lead to recovery after removal or successful treatment of the primarily diseased portion of the gut.

This relationship between the gut and the urinary tract as a postoperative complication, which is so constant, that the French urologist Heitz-Boyer speaks of an "entero-renal symptoms complex," may become effective when long-continued disturbances of intestinal activity exist in a more or less immediate association with the operation. In this connection, one must also think of the effect of an intervention on the part of the physician which, though not immediately surgical, is very consequential in connection with operations, namely, the use of morphine. There is hardly another therapeutic remedy that exerts

such an unfavorable effect upon all the function of the urinary tract and, among others, in the sense of a predisposition to infections: it paralyzes the secretion of the kidneys, produces hypertonia of the sphincteric musculature of the ureter and the bladder sphincter through its spastic components, and makes possible an exodus of bacteria as a result of paralysis of the musculature of the intestine. We believe today that the large majority of all postoperative retentions of urine in the bladder are produced not by the operation on the organs adjacent to the bladder, but by the preoperative and postoperative use of morphine. Very many surgical clinics have, therefore, entirely given up the use of morphine and limit themselves to substitution products. The German chemical industry, however, is endeavoring to remove this spasm-producing radical from the morphine molecule.

When we attempt to draw the therapeutic conclusions from these considerations of the pathology of the infections of the kidney, the first principle established is, that a severe disease of the kidney

may develop under unfavorable conditions from even the most harmless appearing postoperative bacilluria or mild pyuria. Among these unfavorable conditions a motor insufficiency of the efferent urinary passages following many very different types of operation assumes the first place. Inasmuch as this stasis can be determined and treated only by catheterization of the ureters, a careful urological examination in all such cases is the most important requisite of medical knowledge and the physician's duty. It is worthy of mention, that in some cases even the drainage of the bladder by a simple catheter accomplishes also drainage of the kidney. On the other hand, pyelonephritis is still to a great extent outside the pale of our therapeutic ability, as we know little of the predisposing factors of its development. In this case, the therapy is limited to the intensive use of intravenous injections of urotropine. According to our view, a careful control of intestinal motility occupies the center of the stage in all prevention and therapy of colon bacillus infections of the urinary tract.

POSTOPERATIVE EVENTRATION*

T. S. WELTON, M.D.

BROOKLYN, N. Y.

COMPLETE wound breakdown with an escape of part of the abdominal contents is a postoperative complication that happens without apparent rhyme or reason. No operator who does any amount of abdominal surgery will go for long periods of time without having it happen to a patient.

In a search through the literature very little has been found written on the subject. There is no unanimity of opinion as to the causative factors. It has been claimed that sepsis, hemorrhage into the peritoneum, faulty ligatures, poor approximation of the wound edges, excessive postoperative coughing with suture breaking, and syphilis lead to this condition.

Except for a persistent slight elevation of temperature, never more than two degrees one has no warning eventration will occur. When the wound sutures or clips are removed, the skin seems as far as inspection goes, healed by primary union. There is no bulging. The wound looks healthy. Dressings are applied and, as a rule, all thought of the wound is dismissed from the operator's mind.

About two or three days later the operator's house-man or nurse telephones him that the patient's wound has opened and intestines and omentum are spread over the abdomen. The patient may be in mild shock. Often the patient has suffered no sensation of moment.

When observed the wound edges seem dry and necrotic. There is no evidence of hemorrhage. Pus is absent.

As soon as the diagnosis of eventration has been made the attendant, interne or nurse covers the eviscerated contents with sterile gauze wet with warm boric acid

solution. The patient is given grains $\frac{1}{4}$ of morphine sulphate. The operating-room is made ready.

The technic we offer for correcting this complication is not original.

The wound edges are freshened by rubbing them with sterile gauze sponges. The abdominal contents are returned within the abdominal cavity. Two strips of 2 to 4 in. iodoform gauze, each strip from 4 to 6 in. long, are sutured end to end with one interrupted plain catgut suture. This sutured end to end gauze is placed over the intestinal contents presenting through the wound, the ends protruding beyond the upper and lower wound angles. The wound is closed over this gauze using interrupted silkworm sutures. Each suture takes in every layer of the abdominal wall. It is poor practice to attempt closure in layers.

About the tenth day after resuturing, the gauze strip is removed. The plain catgut suture has been absorbed and by pulling on the end protruding from each angle of the wound the gauze comes away in two pieces. About five days later the silkworm sutures are removed.

After the resuturing, the patient is left flat in bed. A Harris or Murphy drip is instituted and continued for three or four days. Small doses of morphine are given for the first forty-eight hours.

As a rule the convalescence is uneventful. We have seen or heard of no second eventration following the closure we have outlined.

The writer has had five postoperative eventrations. All 5 cases were treated by this technic. All wounds subsequently healed. There were no fatalities.

DANGERS IN THE USE OF HYPERTONIC SOLUTIONS IN THE TREATMENT OF BRAIN INJURIES*

JEFFERSON BROWDER, M.D., F.A.C.S.

BROOKLYN, NEW YORK

SINCE Weed and McKibbin¹ reported the changes in brain volume, intracranial pressure, blood pressure and respiration that the pressure of the cerebrospinal fluid could be reduced by following the intravenous injection of

FIG. 1. Average curves, blood pressure and cerebrospinal fluid pressure of 4 normal individuals following intravenous injection of 100 c.c. of 50 per cent glucose.

the intravenous injection of hypertonic solutions, many clinical applications of this phenomena have been devised. Foley and Putnam² reported their experimental observations following the intravenous, oral, rectal and intraduodenal administration of 25 per cent sodium chloride solution. In each instance a distinct fall of cerebrospinal fluid pressure was noted. Comparing the results obtained from the intravenous method and the gastrointestinal route of administration, they found that the extent of the fall in the 2 cases was approximately equal. Sachs and Malone³ investigated

25 per cent saline solution, using dogs as the experimental animal. They concluded that the method was a valuable aid in reducing brain volume in cases of increased intracranial pressure.

Foley⁴ in a later communication reported his observations in the human subject, measuring the changes in the cranial pressure by the tension of a bulging decompression opening. Both the intravenous and oral methods of administration were used, the fall in the cerebrospinal fluid pressure being approximately the same in the 2 instances. He also calls

* Submitted for publication, April 2, 1930.

attention to the fact that there may be medullary depressant effects during or immediately following the intravenous

25 per cent saline solution the present study was undertaken.

Different concentrations of both glucose

FIG. 2. Average curves, blood pressure and cerebrospinal fluid pressure of 5 patients, type 1 reaction.

injection of hypertonic solutions, which was not observed when the gastrointestinal route was used.

From the time of these publications, the methods of treating increased intracranial pressure due to brain hemorrhage and edema associated with trauma to the head began to change from the time-honored sub-temporal decompression or repeated spinal drainage to the intravenous and rectal injections of hypertonic solutions.

That great damage may be done by the routine use of so powerful a dehydrating agent as 25 per cent sodium chloride or 50 per cent glucose solution has been amply shown by the present clinical investigation.

Because of a fatal outcome following the intravenous injection of 60 c.c. of a

and saline solutions have been used, but it has been found by clinical experience that 50 per cent glucose in 75 c.c. to 100 c.c. doses produces the desired effect and causes fewer untoward reactions. Because of this fact glucose in such concentration was used in these experiments.

Subjects: All patients were adult males. Four with traumatic lesions of the extremities were used as controls. In each, the reduction of the cerebrospinal fluid pressure was about the same. The average of the 4 (Fig. 1) has been charted.

Thirteen patients admitted to the hospital because of injury to the head were studied. Four of these observations were not completed because of restlessness of the patients. Of the remaining 9, 8 had been in the hospital for periods ranging

from six to ten hours. These were unconscious or stuporous, but quiet and would remain in any position placed. The ninth

five to thirty minutes before the intravenous injection of the 50 per cent glucose solution was begun. Readings were taken

FIG. 3. Average curves, blood pressure and cerebrospinal fluid pressure of 3 patients, type II reaction.

was in deep coma, bleeding from nose and right ear, absent reflexes and fluid obtained from lumbar subarachnoid space had the appearance of venous blood.

Technic: Throughout the period of observation the patient was kept on the right side with lower extremities flexed, spine flexed and head placed on a pillow in normal relation to the trunk. A large bore spinal-puncture needle was introduced into the lumbar subarachnoid space and attached to a mercury manometer without loss of cerebrospinal fluid. The same size and length connecting tubing was used in each case. A sphygmomanometer cuff was attached to the left arm and diaphragm of a stethoscope fixed in left antecubital fossa. Blood pressure, pulse and cerebrospinal fluid pressure readings were taken every five minutes for twenty-

every five minutes for a variable period following the injection, the average being two hours and fifty minutes.

Results: In this small group of patients there were 3 distinct types of reactions.

In type I group, there were 5 patients who had a moderate decrease in their cerebrospinal fluid pressure associated with slight rise of blood pressure and pulse rate immediately after injection of the hypertonic solution (Fig. 2). There was also improvement of their mental state as evidenced by attempted motor activity and general appearance. None of these regained consciousness, although the cerebrospinal fluid pressure as measured at its lowest point was below the accepted normal. In all the cerebrospinal fluid was pinkish tinted with red blood cells.

In type II group, there were 3 patients

whose cerebrospinal fluid pressure showed a distinct rise following the injection of the hypertonic solution. This was asso-

clearly by the chart, the blood pressure began to fall. This was associated with an extremely rapid pulse, rapid labored

FIG. 4. Curves, blood pressure and cerebrospinal fluid pressure of 1 patient, type III reaction.

ciated with a rise of blood pressure and pulse rate (Fig. 3). The only change noted in their general condition were slight cyanosis of the skin and mucous membrane and increase in the thoracic respiratory excursion. This disappeared after a period of ten to fifteen minutes. These 3 subjects were thought to have severe brain injury. In each the cerebrospinal fluid contained blood in sufficient quantities to produce a cherry red color.

In type III group, there was 1 patient whose condition has already been briefly described. Almost immediately following the administration of the hypertonic solution there was a marked rise of blood pressure, cerebrospinal fluid pressure, and pulse rate (Fig. 4). The respirations were also accelerated, labored and irregular. After thirty-five minutes as indicated

respirations and cyanosis. Death occurred one hour and fifty minutes following the injection of the hypertonic solution. At autopsy there was found lacerations of the under surfaces of the frontal lobes with large amount of subarachnoid hemorrhage (Fig. 5).

DISCUSSION

It would be impossible to draw any conclusions from such a group of cases, but for the fact that the author feels that they are representative of a group of head injuries in a large hospital where about 400 such patients are admitted annually. Many of these are in deep coma when admitted and die within a very short time regardless of what is done for them. Others seriously injured react after one to three hours, but die from twenty-four to

forty-eight hours regardless of what type of therapy is instituted.

These 2 loosely classified groups make

increased cerebrospinal fluid pressure due to intracranial lesions without a recent break in the cerebral vascular system

[FIG. 5. Photograph of brain of patient showing type III reaction. Note extensive subarachnoid hemorrhage.]

up 18 per cent of the total number in 946 consecutive admissions. That increased intracranial pressure alone is not the only factor causing death can be demonstrated in most instances by repeated manometric readings. Often one finds the spinal or cisternal subarachnoid pressure only slightly above the accepted normal when at autopsy extensive cerebral laceration or contusion is present. From clinical and pathological observations it would seem that the terminal factor is intercellular and intracellular edema, particularly of the medulla.

With this pathological picture in mind the logical attempt at therapy would be to change the osmotic pressure of the blood by injecting hypertonic solutions thereby causing a decrease in brain tissue edema. A transitory improvement following such a procedure has been observed in many instances whereas harmful and even fatal results have occurred in others. It must be kept in mind that reducing

is quite a different problem from that due to hemorrhage and edema following trauma. In the former such as tumor, edema surrounding a tumor or edema secondary to trauma without evidence of hemorrhage, hypertonic solutions may be given with a certain degree of safety. In the latter instance where there are findings pointing toward recent blood vessel injury with subarachnoid hemorrhage, one should be very cautious about changing the osmotic pressure of the blood.

ALKALOSIS*

LEON W. McGRATH, M.D., F.A.C.S., AND FREDERICK R. HOOK, M.D., F.A.C.S.

BROOKLYN, N. Y.

IN presenting this paper it is our intention to discuss the early diagnosis and treatment of alkalosis, to emphasize the importance of early diagnosis, and to review a portion of the voluminous literature that has appeared on the subject during the last few years.

The term alkalosis covers a definite clinical picture which may be found in cases that are undergoing medical treatment as well as in postoperative cases. The terms acute paralytic ileus, acute gastric dilatation, gastric tetany and acidosis have been used in the past to denote the syndrome found in this condition.

The condition may occur in cases of intestinal obstruction, the severity varying with the acuteness and location of the obstruction; in cases of peptic ulcer where the patient has been receiving alkaline treatment; and as a postoperative complication following general anesthesia, and to a lesser degree, local and spinal anesthesia.

The patient is mentally alert and apparently unaware of the seriousness of his condition. However, he looks acutely ill, with cheeks sunken and eyes bright. He is apt to talk on trivialities. His skin is cold with beads of perspiration standing out on his forehead. As the disease progresses he shows fibrillary twitching of the hands and feet. The extremities are cold and clammy and the lips and nail beds are often cyanotic. The patient passes into a deep coma preceding death. Vomiting is an early and constant symptom, the vomitus being at first gastric and duodenal contents, and later being fecal in character, light brown in color and of foul odor. Vomiting at first is accompanied by retching but later becomes passive, apparently spilling from the patient's mouth. Hic-cough is a frequent symptom, often being one of the first to develop. In the early stages the patient may pass gas and feces

but soon there is complete cessation of intestinal movement with tympanites. The temperature is normal or subnormal with an antemortem rise. The pulse is weak and rapid from the start and the blood pressure is persistently low. The respirations are shallow and rapid. In short, the clinical picture is that of shock plus intestinal obstruction.

The red blood count is normal, becoming increased later due to dehydration from persistent vomiting. There is a leukopenia. The urine is usually scanty and on examination shows a trace of albumin and a few casts. The non-protein nitrogen in the twenty-four-hour specimen is markedly increased, often as much as 4 or 5 times the normal amount. The urinary chlorides are greatly reduced. Kidney function, as shown by dye excretion, is normal or slightly decreased.

The blood chemistry is characteristic and the most important of the diagnostic points. There is a constant increase in the non-protein nitrogen, a marked decrease in the chlorides and an increase in the CO_2 combining power of the blood.

The pathological findings are not diagnostic. The chief feature is a marked splanchnic engorgement. In the absence of obstruction the intestine is distended with fluid and gas. If an obstruction is present the intestine, if not ruptured, is much distended above the site of obstruction. The intestinal wall is dusky red and may present areas of gangrene. The lumen is full of foul smelling reddish brown fluid teeming with bacteria. The mucosa is deeply injected and presents ulcerations. Histologically the intestinal wall presents marked capillary engorgement and areas of necrosis. Some have described fatty changes in the liver and evidence of toxic nephritis.

The two outstanding features are:

* Read before the Brooklyn Surgical Society, December 6, 1929.

1. The intense toxemia.

2. The marked dehydration accompanied by a constant blood chemistry, consisting of a rise in non-protein nitrogen, a fall in the blood chlorides, and an increase in the CO₂ combining power.

For years numerous investigators have been studying this toxemia and although there is not complete agreement on the subject, the consensus of opinion appears to be that the causative toxin is found in the intestinal content above the obstructive point. The higher the point of obstruction, that is, the nearer it approaches the ampulla of Vater, the more severe is the clinical picture, and the more rapidly the case progresses to fatal termination. It has been shown that the contents from the intestines in obstruction, or from an obstructed intestinal loop, if injected into a laboratory animal, will produce the identical picture of toxemia with death in a few hours. Furthermore, if a dog with a duodenal fistula is given an injection of either the intestinal contents from an obstructed loop, or the intestinal contents from a dog which has been injected with the contents of an obstructed loop, this toxin will be recovered from the duodenal fistula within two hours after the injection, and will be equally as toxic to another animal as were either the contents from the obstructed loop or from the second dog injected. This process can be repeated indefinitely. Cooper,¹ after a most exhaustive study of the literature pointed out the following facts concerning the properties of this toxin:

1. It is held back by an earthen filter but not by paper.

2. It does not pass a semipermeable membrane.

3. It is not destroyed by boiling.

4. It is not destroyed by long digestion with pancreatic juices (seven days).

5. It is not destroyed by autolysis with intestinal mucosa (for months).

6. It is not destroyed by erepsin.

7. It is probably destroyed by hydroly-

sis with 5 per cent sulphuric acid for six hours at 100°C.

8. Repeated precipitation removes its toxicity.

9. It loses its toxicity if dialyzed against physiologic sodium chloride for several hours.

10. It loses its toxicity by repeated filtrations.

11. It loses its toxicity by long standing at freezing temperatures.

12. It is soluble in water.

13. It is precipitated by 5 volumes of alcohol.

14. It is precipitated by albumin.

15. It is precipitated by 60 per cent ammonium sulphate solution.

16. It does not stimulate pancreatic digestion.

Although the toxin has been demonstrated in the contents of the intestine, the origin of the toxin is in doubt. In obstructed loops the toxin has been demonstrated to be both in the blood and lymph draining from the loop. However, the blood of an animal with marked toxemia from obstruction is non-toxic to another animal even though the entire blood is transfused.

In obstruction in the newborn or in sterile closed loops in experimental animals, this toxin is apparently absent, which fact would seem to point to a bacterial origin. Against this, however, is the fact that the higher the obstruction the more severe the toxemia, while the bacterial count is comparatively low in the upper intestines as compared to that in the colon. If the toxemia is bacterial in origin, obstruction of the large intestine should therefore be much more severe than that of the duodenum, which we all know is not the case. Moreover, death from a toxemia apparently identical with that in obstruction is seen in acute strangulation, in complete extirpation of the suprarenals, in bilateral ligation of the ureters, thrombosis of the portal vein and distemper.

What is the origin of this toxin? Experimental work has rather conclusively ruled out the stomach as a source. Elimination

of the bile does not alter the picture. The pancreas cannot be a factor as the same picture is presented in depancreatized dogs. There is much difference of opinion as to whether the secretion of the intestinal mucosa may be the causative factor. There are also many varied opinions as to the part bacteria play, and those who favor it must explain:

1. Why is high obstruction more rapidly fatal than low obstruction?

2. Why does toxin appear with such rapidity (within three hours) after obstruction?

3. Why does toxin appear almost immediately in the intestines of dogs that have received injections of it?

4. Why does the toxin appear in acute pancreatitis, thrombosis of the portal vein, bilateral suprarenalectomy, bilateral ligation of the ureters, and distemper?

Some think that the toxin may arise from partly digested food and that the toxin is derived from protein digestion. The majority of observers think that the toxin is absorbed through the injured gut mucosa.

We shall consider the second outstanding feature of this condition namely, dehydration and blood picture.

Neither the dehydration nor the altered blood chemistry can be considered as cause of death, since death occurs in strangulation and in the other conditions enumerated above without dehydration or a change in the blood chemistry. The dehydration is a result of the persistent vomiting and is directly proportional to it. Also the decrease in the blood chlorides is directly proportional to the vomiting. The loss of the Cl or acid radical causes a disturbance in the acid-base balance with a resulting alkalosis. As a result of the loss of Cl the excess sodium radical is taken up by the acid phosphates of the tissues instead of being neutralized by the Cl from the intestinal tract to form NaCl.

Hence the decrease of blood chlorides is directly proportional to the loss of Cl

by vomiting. As a result of the loss of the acid radical Cl, there is a rise in the carbonic acid radical of the blood, this being a natural attempt of the body to maintain acidity of the blood at its proper level. The increase in the CO₂ combining power of the blood varies inversely as the decrease in the blood chlorides and is also directly indicative of the degree of alkalosis.

The rise in non-protein nitrogen is the result of tissue metabolism with destruction of the proteids. It cannot be explained by dehydration since it has been repeatedly shown that the increase in the urea is relatively many times greater than the degree of dehydration. Further, it cannot be explained by retention, since the kidney function is normal and the urinary output is normal or only slightly decreased. The cause of this proteid destruction is unknown. However, the increase in the non-protein nitrogen in the blood is directly proportional to the decrease in the blood chlorides and to the increase in the CO₂ combining power, and all three respond correspondingly to the same line of treatment.

So much for the toxemia and dehydration, but what has happened to the unobstructed bowel that fails to transport fluids and gas? Alvarez and Hosoi² showed by experimental work on animals that section of the spinal cord distal to the fourth dorsal segment caused such a strong stimulus to peristalsis that after a few hours the bowel tends to empty itself with repeated rush waves. In animals with the terminal ileum injured they saw few rush waves and in some they seemed to be stopped entirely, even though the lumen of the bowel was unchanged and the rhythmic movements were active and the muscles efficient. Alvarez and Hosoi believe therefore, that we must find a new term for the type of ileus which is not due to mechanical obstruction or narrowing of the gut lumen. It is not paralytic because the muscle is active and apparently in good working order,

and it is not dynamic since there are none of the white ring-like contractions that sometimes obstruct the bowels in children. They offer the explanation that there is a flattening, or reversal, of the normal gradient of forces, and an excess of inhibition, and suggest the term flat gradient ileus for this type of condition.

TREATMENT

In comparison with the many and varied opinions as to the cause and origin of the toxemia in alkalosis, we find that in the treatment of the condition most observers are agreed, at least upon the essentials.

Care should be used in the administration of alkaline drugs in the treatment of peptic ulcer especially in the presence of pyloric obstruction or kidney damage.

In preoperative cases where there is intestinal stasis and no emergency exists, medical treatment consisting of repeated stomach lavages and the administration of NaCl should be carried out until the blood chemistry has been brought within normal limits.

Preoperative purgatives are to be condemned as they weaken the muscles and disturb the mechanisms that remove the gas.

Alvarez and Hosoi² demonstrated that distending and irritating enemas especially with glucose solution tended to reverse the gradients and produce more back pressure and reverse peristalsis.

As little morphine should be used as possible as in many persons it increases the tendency to reverse peristalsis. Barbitol derivatives do not upset the gradients and are probably the best substitutes we have for morphine.

Some think that ether upsets the gradients and should be replaced by other forms of anesthesia. However, we have seen several cases of alkalosis develop following both spinal and local (procaine) anesthesia.

Unnecessary and rough handling of the abdominal viscera is advised against.

As to the various drugs that are commonly in use, atropine and strychnine are unreliable and ineffective. Nicotine would be an ideal drug if it were not so highly toxic, as it blocks the passage of nervous impulses through the sympathetic ganglia. Pituitrin, when given in large doses of physiologic NaCl will stimulate peristalsis but it is as apt to do harm as good. Eserin is not reliable. Alvarez and Hosoi² state that choline is a drug that gives great promise. Von Magnus³ and his pupils in their experimental work have much evidence to prove that it is a normal constituent of intestinal muscles and is concerned in some way with maintaining peristalsis. The drug must be chemically pure as it tends to break down into toxic substances. Merck and Kahlbaum supply it in ampules containing 600 mg., and put up in this manner it will keep for several years. For a man weighing 60 kg., the 600 mg. should be added to at least 250 c.c. of physiologic salt solution and run into a vein so slowly that the process will take at least seventeen minutes. If the patient complains of flushing, dyspnea, dizziness and salivation, and the pulse becomes slow, the container should be lowered. We have had no experience with this drug.

As to food some think that these patients should be fed for the purpose of stimulating peristalsis, and suggest that meat be given them as it probably has the most stimulating effect on the tone of the gastrointestinal tract. Our experience with feeding has led us to believe that it only aggravates the condition unless the toxemia and vomiting have previously been relieved by lavage and NaCl.

Much difference of opinion exists as to the value of the antitoxin of *Bacillus welchii*. Morton and Stabin,⁴ in their experimental work found that the toxin of *B. welchii* has a bearing on intestinal obstruction and that the antitoxin appears to be specific in its action, since other forms of antitoxin are not effective. Owings and McIntosh⁵ found that the life of dogs in high obstruction was not

prolonged by antitoxin of *B. welchii* and immunization of dogs of the toxin of *B. welchii* did not prevent a fatal outcome in those given a minimum lethal dose of loop toxin. Stabins and Kennedy⁶ experimentally recovered the organisms of *B. welchii* from the jejunum 10 in. distal to the ligament of Treitz in 17 per cent of their series at the time of artificial obstruction at this level. After the development of toxic symptoms the organism was recovered proximal to the obstruction in 94 per cent of their animals. Williams⁷ reports very favorably upon the use of the antitoxin at the St. Thomas's Hospital. It was administered to 18 of the most severely ill of a series of 256 consecutive cases of obstruction following acute peritonitis. There were three deaths, making a mortality rate of 1.17 per cent. A control series of 111 cases at the same hospital which were not given the *B. welchii* antitoxin showed a mortality rate of 6.3 per cent. The antitoxin was given in addition to operative relief in 54 cases of acute intestinal obstruction, and there was a mortality rate of 9.3 per cent as opposed to the rate of 24.8 per cent in a series which did not receive antitoxin. Bower and Clark⁸ report favorably upon its use, having administered it in 9 cases of acute intestinal obstruction, 11 of diffuse suppurative peritonitis, and 5 of suppurative cholecystitis. They found their patients less restless; the pulse rate was diminished, the temperature reduced, abdominal distention became less, and bowel movements began earlier.

Bonney⁹ in 1910, was the first to advocate drainage of the jejunum, and since that time jejunostomy has been used with rather indifferent success. Van Beuren and Smith,¹⁰ in reviewing the cases of enterostomy performed in acute ileus at the Presbyterian Hospital from 1914 to 1923, and the Roosevelt Hospital from 1910 to 1919, showed a higher mortality rate in the enterostomized cases than in the entire group, but were of the opinion that enterostomy had been reserved as a last resort

in the most critical cases, and therefore had not a true bearing on the efficacy of the treatment. Dudley¹¹ states that obstruction of the paralytic type accounts for 40 per cent of the deaths following operation for acute appendicitis in the presence of diffuse peritonitis, and believes that jejunostomy is the most efficient means of combating the toxin. Orr and Haden¹² found enterostomy of no avail in fulminating general peritonitis. In peritonitis of the lower part of the abdomen it is life-saving and in all doubtful cases should be done. Bartlett¹³ states that the high mortality reported following enterostomy is the inevitable concomitant of its use in patients already dying. He uses spinal anesthesia in determining when to perform an enterostomy. If within fifteen minutes after the injection of the spinal anesthetic, passage of gas and feces and disappearance of abdominal distention does not occur, enterostomy should be performed immediately, thus taking advantage of the anesthesia already produced. Longer delay permits progressive depletion of the NaCl and water reserves, interference with circulation of the gut, absorption of toxins from the intestines, and advancement of those other processes which singly or in combination cause death.

Spinal anesthesia in the treatment of intestinal obstruction has many proponents. Greig¹⁴ reported favorably on its use in 400 cases. Studdiford¹⁵ especially recommends it in dynamic ileus but also uses it in all types of obstruction to be followed by operation if necessary. Markowitz and Campbell¹⁶ have used spinal anesthesia in the laboratory on dogs after producing ileus by chemical or traumatic means, and have observed peristalsis carefully by means of barium meals and the fluoroscope, when they have noted that peristaltic movements commenced soon after the spinal anesthesia and persisted in some instances for over twenty hours. They offer the conception that paralytic ileus is a reflex inhibition of bowel movements. Starling¹⁷ states that stimulation

of the splanchnic nerves causes complete relaxation of the intestine, while stimulation of the vagus causes increased contraction following a brief period of relaxation. He also suggests that the relaxed condition of the intestine in many abdominal conditions is probably due to reflex stimulation of the splanchnic nerves which nullifies the motor action of the vagus.

The probable explanation of the effect of spinal anesthesia in ileus is that splanchnic inhibitory reflexes are blocked so that the vagus motor reflexes have full power. It is well to keep in mind that spinal anesthesia will not be effective if the patient is under the influence of morphine.

The efficacy of the treatment of alkalosis by the use of hypertonic solution of NaCl has been proved both experimentally and by clinical use. NaCl in 2 to 25 per cent solution intravenously acts as a strong intestinal stimulant. It has been shown beyond a doubt that water alone will not influence alkalosis, and also that KCl, NH_4Cl , CaCl_2 , and MgCl_2 are not only useless but increase the severity of the alkalosis. Anderson and Rockwood¹⁸ reported 90 cases of low blood chlorides associated in most cases with abdominal lesions treated with hypertonic saline solution intravenously with a reduction of the operative mortality of more than one-half. Foster and Hausler¹⁹ brought out the fact that loss of chlorides is apt to occur in what they call the "critical period," which corresponds with the healing period of intestinal wounds in experimental animals, and lasted four or five days after operation. They therefore suggested keeping the chlorides at their proper level for five days. This conception we think is well founded and in practice has given us excellent results. It has been our custom to give 1000 c.c. of normal saline intravenously plus 100 to 500 c.c. of 2 per cent NaCl solution and 40 to 50 gm. of glucose daily. The glucose is given in 5 per cent solution with the normal saline. This we have found controls the toxemia in the average case quite effectively.

The treatment should be checked by blood chemistry examinations whenever possible, but where such procedures are not easily available the course of the treatment may be checked by the clinical picture which improves as the chlorides approach normal. In experimentally produced general peritonitis Orr and Hayden¹² were able to keep animals alive 3 times as long with ileostomy plus 1 per cent NaCl as with ileostomy alone, and they state that no treatment for peritonitis should be given to the exclusion of large quantities of saline solution to relieve the dehydration and hypochloremia.

In addition to the intravenous therapy it is advisable to drain the upper intestinal tract of its toxic content, either by repeated gastric lavages or duodenal drainage. It is surprising how quickly the hiccough, the vomiting, and the clinical picture of shock subside after a few hours of duodenal drainage. However, we must keep in mind that in draining the intestinal tract we are predisposing to further dehydration and hypochloremia and must make up for it by giving saline intravenously.

If tetany develops, calcium chloride should be given in addition to the NaCl. This is administered most effectively in 5 c.c. doses of 10 per cent solution intravenously, and repeated every two hours until controlled.

Formerly the accepted treatment in cases of persistent vomiting in intestinal obstruction, postoperative ileus and allied conditions was the use of sodium bicarbonate, either intravenously or by proctoclysis, and the term acidosis was generally accepted for the clinical picture. With our present knowledge of the blood chemistry findings further attempts at alkalization are certainly contraindicated. Whatever benefits may have been observed following the use of sodium bicarbonate was probably due to the introduction of the sodium radical.

It is quite natural for a patient who has had an abdominal operation to prefer to lie quietly in bed on his back, and those

with tympanites usually insist on having the chest and head elevated. Unless there are some contraindications we believe that patients should not only be encouraged, but should be forceably moved from side to side, which will tend to shift the gas from one part of the intestines to another. Moreover, it is reasonable to expect that gas trapped at the splenic flexure might be thrown into the rectum where it could be passed, by simply elevating the hips above the mid-portion of the body.

The following cases are reported:

CASE I (33442). White, obese, male, age thirty-four years.

Admitted to hospital on December 6, 1928, with a history of having developed generalized abdominal pain four days previously which soon settled in his right lower quadrant. Temperature was 101.6, pulse 120 and respiration 18. The leukocyte count was 13,400 with 91 per cent polymorphonuclears. Urine was positive for albumin and hyaline casts. A gangrenous appendix was removed under ether anesthesia on the day of admission. On the second postoperative day he complained of belching and abdominal distention and during the night began to vomit. The stomach was lavaged and the Rehfuß tube left in place. Glucose was given intravenously and normal saline by hypodermoclysis. Strychnine sulphate and pituitrin were given repeatedly without any appreciable results. On the fourth postoperative day a bronchopneumonic patch was found at the right base. Glucose intravenously, normal saline by hypodermoclysis and proctoclysis were continued daily, and the first bowel movement was secured on the seventh postoperative day. Convalescence from there on was uneventful except for a colon bacillus infection of the abdominal wall. Had hypertonic saline been given intravenously instead of normal saline by hypodermoclysis recovery undoubtedly would have been much more rapid. Blood chemistry examinations were not done in this case.

CASE II (32892). White, male, fifty-five years of age, was admitted on October 30, 1928, with a diagnosis of recurrent left inguinal hernia and old fracture deformity of left clavicle. Urine was reported as albumin positive 1 plus and hyaline casts 1 plus. Repair

of left inguinal hernia was done on December 19, 1928. Thirty-six hours after operation complained of distention, was nauseated and vomited a small amount of greenish material. Gained some relief from an enema and rectal tube. Was given 1000 c.c. of normal saline intravenously. Vomited large amounts of greenish fluid on the following day and duodenal drainage was instituted and 1500 c.c. of normal saline given intravenously. On December 23, four days after operation, blood chemistry showed non-protein nitrogen 28 (mg. per 100 c.c.) and chlorides 363, (mg. per 100 c.c.) and he was given 1000 c.c. of normal saline intravenously. On the following day vomiting ceased and bowels moved well. On December 25 he again complained of marked abdominal distention and was given 1500 c.c. of normal saline and on the following day the blood chemistry showed non-protein nitrogen 18.9 (mg. per 100 c.c.) chloride 400 (mg. per 100 c.c.) and CO₂ combining power 53 (volumes per cent). On this date he was given 100 c.c. of 2 per cent NaCl and 500 c.c. of normal saline after which distention disappeared, flatus was passed and patient went on to an uneventful recovery. Strychnine, atropine, physostigmine, pituitrin and numerous enemas were given during the several days without any appreciable improvement. This case is cited to show that sufficient NaCl was not given early to control the toxemia.

CASE III (4415). White, male, forty-three years of age, entered the hospital for treatment of a right inguinal hernia of one year's duration. Physical examination was negative except for a moderate sized right inguinal hernia and a markedly relaxed ring with strong impulse on the left side. The urine showed 1 plus hyaline casts but otherwise was negative. The patient had had some trouble with his appendix previously and requested that it be removed at the same time that his hernias were repaired. Both hernias were repaired under procaine anesthesia on October 2, 1929 and the appendix removed through the right hernia incision, the three operations requiring one hour and twenty-five minutes. On the morning following operation the patient complained of considerable distention. He had been given three hypodermics of morphine sulphate gr. $\frac{1}{4}$ for pain in the preceding twenty-four hours. Early in the second postoperative day he suddenly went into a state of shock and vomited a large

amount of dark brown fluid. He was placed between blankets and artificial heat was applied. The stomach was lavaged and the patient given saline and glucose intravenously, after which he reacted well. On the third postoperative day the patient was still considerably distended and had hiccough. Blood chlorides were 445 (mg. per 100 c.c.); saline and glucose were given intravenously. Condition was worse on the fourth postoperative day and the blood chemistry showed nonprotein nitrogen 28 (mg. per 100 c.c.) chlorides 429 (mg. per 100 c.c.) and CO_2 combining power 44 (vol. per cent). A jejunostomy was performed under procaine anesthesia with the release of a large amount of gas and foul smelling fluid. On the fifth postoperative day he was not improved and the jejunostomy tube was draining very little. Saline and glucose were repeated intravenously. On the sixth postoperative day there was marked dyspnea; temperature, pulse and respiration were markedly elevated. He passed a little gas per rectum and about 1500 c.c. of fluid fecal matter through the jejunal tube. The blood chemistry at this time showed non-protein in nitrogen 28 (mg. per 100 c.c.) chlorides 445 (mg. per 100 c.c.) and CO_2 combining power 48 (vol. per cent). Glucose and saline were given intravenously and a cecostomy performed under procaine anesthesia as a last resort. The patient went into coma and died a few hours later. The autopsy findings were: Postoperative atelectasis, both lungs; chronic adhesive pleurisy; hypostatic bronchopneumonia; pulmonary edema; myocardial degeneration; cardiac dilatation; postoperative paralytic ileus, degeneration of the parenchymatous organs; adenoma of the prostate; and passive congestion of the viscera.

CASE IV (31404). White, male, age thirty years. Has a history of "stomach trouble" for past six years; appendix was removed in 1923. He has had several courses of Sippy diet. Had an attack of hematemesis and tarry stools one year ago, since which time he has been very weak. While on Sippy diet under observation in the hospital on July 21, 1928, he developed tetany which was controlled by normal saline and glucose intravenously, and calcium lactate grains x by mouth every hour. Gastric resection for obstructing pyloric ulcer was performed on August 8, 1928, from which the patient with the aid of glucose and saline intravenously made an uneventful recovery.

CASE V (33744). White, male, age thirty-one years, admitted to hospital with a history of pain in right chest of one month's duration. X-ray showed a dense shadow in the axillary portion of the right lung field whose convex border, together with evidence of pleural thickening in the adjacent costophrenic sinus, was suggestive of an old encapsulated pleural exudate. The adjacent lung markings suggested atelectasis. Patient had an occasional chill, and temperature was of the septic type, ranging from 100 to 104°F. Thoracotomy was performed on January 8, 1929, which revealed a trabeculated cavity filled with blood clots. Drainage was blood tinged for several days, gradually becoming purulent. Temperature continued to be of the septic type and fourteen days after operation he developed hiccough and vomited. Hiccough continued more or less continuously for five days and the patient became delirious. At this time the blood chemistry showed non-protein nitrogen 28 (mg. per 100 c.c.) and chlorides 346 (mg. per 100 c.c.). He was given 250 c.c. of normal saline and 200 c.c. of 2 per cent saline intravenously which was repeated on the following day, after which his symptoms rapidly disappeared and convalescence was uneventful from then on.

CASE VI (4121). White, male, age thirty-one years. Gives a history of typical gall bladder colic over a period of ten years. A chronically diseased gall bladder with a stone 1 cm. in diameter blocking the cystic duct, and the appendix were removed under spinal anesthesia on November 7, 1929. Twenty-four hours after operation patient vomited a large amount of brownish fluid. Blood chemistry showed non-protein nitrogen 15 (mg. per 100 c.c.) and chlorides 470 (mg. per 100 c.c.). Stomach was lavaged and hypertonic saline and glucose given intravenously with relief of all symptoms and an easy convalescence from then on.

CASE VII (5334). White, male, thirty-six years of age. Appendectomy with exploration was performed under spinal anesthesia on November 26, 1929. Twenty-four hours after operation patient was comfortable except for some gaseous distention which was relieved by an enema. Forty-eight hours after operation he began to hiccough, became distended, and vomited large amounts of greenish fluid. Blood chemistry showed urea nitrogen 22.5 (mg. per

100 c.c.) chlorides 429 (mg. per 100 c.c.) and plasma CO_2 51 (volumes per cent). After gastric lavage and hypertonic saline and glucose intravenously patient passed flatus freely and the abdomen became soft.

In conclusion we wish to make a plea for the early recognition of the toxemia associated with paralytic ileus. Those who have to do with the post-operative care

of patients should be on the lookout for the early signs that precede the characteristic changes in the blood chemistry. These are usually: a feeling of fullness in the epigastrium, belching, heartburn, hic-cough, a craving for water, and a decrease in the urinary output. It is at this stage that treatment terminates so happily, both for the patient and the surgeon.

CEMENT-STARCH MIXTURES AS A SUBSTITUTE FOR PLASTER OF PARIS IN THE TROPICS*

K. P. A. TAYLOR, M.D.

PUERTO ARMUELLES, PANAMA

DETERIORATION OF PLASTER IN THE TROPICS

SURGEONS working in tropical countries where the humidity is high often witness the rapid deterioration of unused plaster of Paris, resulting from absorption of moisture. This is particularly noticeable when the contents of 5 or 10 lb. containers are only partly consumed, as often happens when the use of plaster is not a daily or even a weekly occurrence.

In these circumstances, it is often found that the plaster has lost its smooth amorphous character and it becomes coarsely lumpy or mixed with hard, irregular granules. This deterioration is sometimes not apparent until the bandages are applied, when it is observed that the solid portions of the plaster remain dry and unaffected by immersion; the layers of bandage fail to cohere, and the resulting cast readily bends or cracks. Some grades of plaster appear to undergo this important change without exposure and as a result of aging alone, as the alteration may be seen in plaster taken from freshly opened containers which have been hermetically sealed. There is evidence, therefore, that such aging of hermetically sealed plaster takes place more rapidly in tropical localities than in climates where there is less moisture in the atmosphere.

SPECIAL METHODS ADOPTED IN USING PLASTER OF PARIS

To overcome these difficulties the following rules are commonly observed in the tropics: (1) Coarsely deteriorated plaster is discarded. (2) Doubtful plaster is used very liberally in rolling bandages, and about 50 per cent more is applied than in temperate climates. (3) Standard gauze bandage is used instead of crinolin or other wide-meshed material, in order to hold the increased plaster content. (4) Additional

plaster is liberally applied during the application of a cast. (5) Reinforcements of metal or wood are frequently placed at points of stress, particularly in a hip cast. To assure drying, water at 110°-120°F. is employed in the bandage basin and a half teaspoonful of salt is added to it.

VARIETIES OF PLASTER OF PARIS

Certain French preparations of plaster marketed in 500-gm. sealed tins are entirely free of the objections mentioned. These products are of the finest quality and possess an added advantage in being packed in comparatively small containers. Best grade French plaster of Paris, however, is not always obtainable; and, moreover, in some countries a high import duty prohibits the economic use of this product.

SUBSTITUTE FOR PLASTER

A common indication of the necessity for providing a plaster substitute is the discovery that all of the plaster on hand has deteriorated to a degree which makes its effectiveness doubtful. This experience has probably been the lot of most surgeons working in isolated localities in the tropics where quick access to a supply of fresh plaster is not always available. When such an emergency situation is encountered, fixation by splinting or extension is not always a satisfactory alternative. The writer has found that mixtures of Portland cement with starch, with certain reservations, fulfill the requirements for an emergency or semi-permanent substitute for plaster of Paris.¹

THE CEMENT-STARCH CAST

For most purposes, a mixture of equal parts by volume of Portland cement and

¹ Ryerson, E. W. The celluloid cast described by Ryerson is expensive and requires several days to complete. *J. Bone & Joint Surg.*, 8: 517-518, 1926.

* Submitted for publication, April 15, 1930.

laundry starch will prove satisfactory. These materials are freshly mixed, triturated if lumpy, spread thickly on a gauze

FIG. 1. Cement-starch cast used for fixation and extension in fracture. Dislocation of third and fourth cervical vertebrae. When removed one month after application, this cast was in good condition. Composition: Cement 1 part; starch 2 parts.

bandage, rubbed smooth and loosely rolled. The bandages are placed in warm water (salt is omitted), gently compressed to insure exit of air bubbles and applied exactly as are plaster bandages. Cement-starch powder and water are thoroughly rubbed into the growing cast. The finished model is smoothed and polished with starch-and-water paste. Casts for the arm or leg should be at least 1 cm. thick after rubbing; and for the body, thigh and hip, they should be proportionately heavier.

For a light-weight cast, subjected to little strain, the mixture may be made of two parts by volume of starch to one part of Portland cement; while for a heavy cast, which may be subjected to considerable tension, the proportion may be reversed.

These casts generally require from twenty-four to thirty-six hours to become thoroughly dry and hard. New types of quick-hardening cement materially reduce the time of setting. During this period, immobility must be assured by cooperation of the patient. Drying may be hastened by the application of hotwater bottles to the cast, by exposure to sunlight, by hair-drying apparatus, or by utilizing one or more 200 cp. electric bulbs.

COMPARISON OF CEMENT-STARCH WITH PLASTER OF PARIS

Casts made in the manner suggested compare favorably with those constructed of the ordinary grades of domestic plaster of Paris or dental plaster. They are made of materials which do not deteriorate and which are always available. They are heavier and somewhat softer, and tend to become more moist than plaster casts. They bend readily, but are not so prone to crack. They appear to wear as well as ordinary plaster casts and are easier to remove in either the dry or wet state. Removal is best accomplished after soaking the cast in water to soften and dissolve its starch content. The moistened cement bandage is easily cut with a cast knife or cutter.

Economically, the cement-starch cast is of decided advantage. For example, in Guatemala, the cost of Portland cement is \$0.0132 per pound, and of starch is \$0.119 per pound; while plaster of Paris (French grade) is \$0.30. Furthermore, there is a large percentage of loss from deterioration when ordinary plaster of Paris is used; this must be taken into consideration in making an estimate of the comparative gross cost of the product.

CONCLUSIONS

1. Ordinary grades of plaster of Paris are subject to rapid deterioration in tropical climates, which renders them unsuitable for exacting use.
2. High grade French plaster of Paris, packed in small containers, is stable and should be given preference when possible.
3. Mixtures of Portland cement and starch have been used satisfactorily as substitutes for plaster of Paris. The materials are cheap and readily available, and are not subject to deterioration.
4. The cement-starch cast compares quite favorably with casts made of the ordinary grades of plaster of Paris and is superior to those made of deteriorated plaster.

INTRAVENOUS UROGRAPHY

BETTER VISUALIZATION WITH COMPRESSION*

SAMUEL LUBASH, M.D.

NEW YORK

HISTORICAL

SINCE 1897 when Tuffier first suggested the use of an opaque internal catheter, the profession has been

raphy, through whose efforts the foundation of this great work was laid.

From 1912 to 1923, the common practice of injecting a 12 per cent sodium iodide

FIG. 1. Hickey bag employed in intravenous urography.

floundering about in an effort to reach the ideal method of clearly demonstrating the outline of the genitourinary tract on the x-ray film. The interim between 1897 and 1912 is now of historical value only. Such men as Klose, Voelcker and von Lichtenberg, Keyes, Uhle and Pfahler, Doderlein and Kronig, Burkhardt and Polano, Dietlen, Kelly and Lewis, Baker, Oehlecker, Stanton and Bruce, Thomas, Braasch, Kidd, Fowler, Schramm, Childs and Spitzer, Alberran and Ertzbischoff, Nogier and Reynard, will always be remembered as the true pioneers of uro-

solution through the catheter seemed the standard method of choice for this work. Urology had now become an independent field of medicine, and urologists seemed satisfied with this method. But in 1923, unrest again prevailed, and now knowing the true limitations of the retrograde method, a new technic of visualization by the intravenous route was sought. The names of Sutherland, Scholl, Osborne, Rowntree, Rosenstein, von Lichtenberg, Volkmann, Lenardouzzi, Pecco and Roseno will always be associated with the newer thought. Although unsuccessful in their

attempt, their work will always remain memorable. It remained for Swick in 1929 to give us a non-toxic drug for intravenous

increased density not only of the kidney, but of the entire urinary tract, seems striking in comparison.

FIG. 6. Poor functioning left kidney and kinked right ureter; hydronephrosis and hydroureter on right side.

urography, to which was given the name uroselectan, and with it another rung in the ladder of urology has thus been completed.

PRESENT METHOD

The purpose of this paper is to emphasize three important points with reference to the method employed with intravenous urography, viz: (1) compression before and during the x-ray exposures; (2) increase in the dosage of uroselectan; (3) the withholding of urination.

Although mentioned by the originator in his memorable contribution, greater emphasis seems essential at this time. Notwithstanding the fact that visualization without compression may be quite satisfactory in some clinics, with us at least compression has now become an essential part of this new method. This additional effort is more than compensated for by the advantageous results obtained. The

FIG. 7. Normal pyeloureterogram.

Compression. The method employed is quite simple. The ordinary Hickey rubber bag is employed as demonstrated in Figure 1, and placed over the bladder region. Enough pressure is used to make the patient just comfortable. This is instituted immediately after the last injection of uroselectan, and allowed to remain until after the first film is taken, then released partly, but retightened within ten minutes before and through the exposure of the second film. The pressure is now entirely released but is reapplied ten minutes before the third, fourth and succeeding exposures, and held compressed during this act. There is no question in our minds that better visualization is obtained by this means, but what the rationale is we are not prepared to say.

Dosage. For the adult Swick now suggests a 60 gm. dose of selectan instead of the original 40 gm. dose. The method of dissolving and distilling is carried out as employed by Swick, viz.: dissolving the

drug in warm double-distilled water to a volume of 110 c.c., filtering this twice through ordinary filter paper, and sterilizing the solution in a water bath at 15 lbs. pressure for one-half hour. With the increased dosage we have found no untoward effects, but much better visualization.

Urination. Although discomforting to some patients, we try not to allow the passage of urine until after the second exposure. If the desire becomes unbearable, by allowing the passage of a small quantity between the first and second exposures, enough comfort may be obtained to carry on without further interference. Compression, no doubt, adds to this extreme desire, so that with slight releasing of the bag, this discomforting feeling may pass.

CONCLUSIONS

1. That all these three points aid

materially in producing a denser roentgenogram is without doubt.

2. What the rationale for this improvement may be we are not prepared to say.

3. Increased dosage to 60 gm. has no untoward effects on the patient.

4. External compression over the bladder as here outlined does improve visualization.

5. The value of intravenous urography, as devised by Swick, is tremendous. Only time will evaluate its true worth.

I wish to thank Dr. A. Wolbarst for having made this work possible by supplying the uroselectan employed and Dr. I. Seth Hirsch for his kind cooperation.

ROENTGENOLOGICAL DIFFERENTIAL DIAGNOSIS OF SPINAL PATHOLOGY*

W. I. LEFEVRE, M.D.

CLEVELAND, OHIO

THE spine is the most difficult part of the skeletal structure to subject to adequate x-ray study. This is due to its complex structure and its anatomical relationship, causing superimposed shadows which interfere with detail. Clear detail is the prime requisite for satisfactory roentgenography.

Improved appliances and added accessories in recent years have made it possible to obtain splendid x-ray films in both the antero-posterior and lateral views of the spine. The value of the roentgenogram in the diagnosis of spinal pathology is no longer debatable. The intent of this paper is to show its relative value in different pathological conditions; however, these observations will be confined to the bony structure of the adult spine. Pathological conditions in children are worthy of separate study, while diagnostic measures in diseases of the cord or soft tissues require special technic not within the scope of this paper.

For convenience of consideration, the pathological conditions are divided into 3 classes, as follows:

1. Anomalies and curvatures of the spine.
2. Diseased conditions of the spine.
3. Traumatic injuries to the spine.

Anomalies or congenital malformations may occur in any part of the spine, but certain areas predominate, arranged in numerical value in the following order: The fifth lumbar vertebra, the upper segment of the sacrum, the seventh cervical vertebra, the lower segments of the sacrum, and the first lumbar vertebra. The coccyx normally varies considerably and is not included. Variations in the rest of the spine are exceptional.

The first mentioned, the fifth lumbar, is

of unusual interest. Malformations frequently occur and may affect the body, laminae or processes. Occasionally the transverse processes are fused with the sacrum, producing the so-called sacralization of the spine, more often unilateral, rarely bilateral. These processes may also press upon the inner angles of the wing of the ilium; however, an overlapping shadow does not indicate such a condition, as these processes are usually anterior to the ilium with about one-fourth in. clearance. The articular surfaces between the fifth lumbar and the sacrum are often times hazy in the x-ray film, due to deposit in this region, not necessarily pathological, but may be painful if inflamed. The irregularity in the development of the two sides of this vertebra frequently causes a slight tipping of the pelvis. Occasionally the fifth lumbar vertebra slips forward at the lumbosacral articulation, a condition called spondylolisthesis. Usually the angulation is increased so that the upper portion of the sacrum may be almost at a right angle to the lumbar spine, while the normal angulation is about 45 degrees. This can be detected with a good lateral film of this region. Sometimes the fifth lumbar is replaced by an extra, or sixth, lumbar vertebra. This portion of the spine is frequently malformed and quite subject to injury. Perhaps it was originally designed by the all-wise Creator for our horizontally-spined ancestors, slowly evolving toward greater perfection for the comfort of future generations.

The upper segment of the sacrum frequently shows an incomplete fusion of the arch. This in itself is of no pathological significance, but this vertebral segment seems to be more subject to trauma than the normal. The transverse processes of

* Submitted for publication May 19, 1930.

the seventh cervical vertebra are occasionally elongated or an extra rib formed. This may be unilateral or bilateral and, if of any length, may produce pain from pressure on the nerves or soft tissues. The lower segments of the sacrum are sometimes incomplete, usually unilaterally. The transverse process of the first lumbar are sometimes ununited, usually unilateral but frequently bilateral, or prolonged into an extra rib. The former condition may be mistaken for a fracture of the transverse process, but should be distinguished by the smooth oval appearance of the articular surfaces. True these conditions may cause or contribute to pathological ailments, but they are very often observed roentgenographically in patients free from symptoms. These defects can only be diagnosed during life by means of the x-ray.

The normal contour and degree of motion of the spine can readily be observed by the roentgenologist. The motion between any two vertebrae (except the atlas and axis) is quite limited, although the movement of the spine as a whole is considerable. It can be bent or twisted and if roentgenographed in that position, or if the ray is off center or angulated, the normal spine would appear curved, rotated or deformed. This is worthy of note in medico-legal cases. A fake curvature or rotation can usually be detected by observing the position of certain landmarks. The lower spine should always include the entire pelvis and the symmetry of the spines of the ischae observed. The dorsal spine should include the clavicles and their relative position observed. The structural formation of the bodies of the vertebrae should also be noted.

In a true structural curvature of the spine, there is always rotation of the spine in its vertical axis, with the bodies toward the convexity. Usually this rotation is more pronounced than the curvature. The spinous processes may be in fair alignment; consequently the roentgenogram is the logical way of determining the true degree

of deformity. The normal spine can be flexed equally to either side of the center of the spinal plane, while the structural scoliosis cannot be forced to the opposite side beyond this center plane. This can be demonstrated roentgenographically. A kyphosis always shows compression of some of the vertebral bodies over their anterior portion, conforming to the curve. In a lordosis the reverse is true. This condition is easily checked with the x-ray film.

Forward or backward slipping of the sacroiliac articulation is hard to confirm. A stereoscopic anteroposterior film, using the Potter-Bucky diaphragm, with vertical shift, and guide wire lines transversely across the film at regular intervals, will give the best perspective. Lateral films of the dorsal spine should be slightly oblique, thus partially avoiding overlapping shadows. Lateral views of the cervical region are best obtained by resting the upper arm against the film, tube centered over the shoulder at 50 inches distance.

DISEASE CONDITIONS

The spine is subject to practically every disease which may affect any portion of the bony structure. Two diseases, arthritis and tuberculosis, stand out preëminently, and coincidentally their roentgenographic appearances are practically pathognomonic. In adults, the various forms of arthritis predominate, but tuberculosis easily heads the list when diseased conditions in children are included. Clinically, tuberculosis of the spine is probably the easier to diagnose, especially after the disease has reached the destructive or deforming stage. The body of the vertebra is usually subject to attack, first the anterior portion, then the epiphysis under the cartilaginous discs, with early invasion of these discs, producing a collapse of the body into a wedge shape, with sharp angulation of the spine at point of involvement. Tuberculous disease *per se* is purely destructive, but a subsequent or mixed infection will produce an exudate with

thickening or callus deposit. The roentgenographic appearance is characteristic and scarcely can be mistaken. Arthritis is usually classed as atrophic or hypertrophic, with a severe mixed form extensively involving the spine, hips and other joints, called arthritis deformans. This latter is easily diagnosed clinically; the former is difficult to diagnose clinically, but rather easily diagnosed roentgenologically. The atrophic form usually affects the lower spine and sacroiliac regions, producing a diffuse thinning out of the bone, affecting the articular surfaces, cartilage and ligaments, causing severe pain. The hypertrophic form may affect any portion of the spine; the bodies of the vertebrae are usually involved, with exostoses or spurs projecting from their angles; those from the inferior angle project downward, while those from the superior angle project upward, sometimes called "parrot's beak," due to this peculiar formation. At times, this condition is painful, frequently causing little pain relative to the amount of involvement. The roentgenographic appearance is quite characteristic.

Syphilis offers 3 forms for classification: (1) arthralgia, causing pain without destruction of bone and not recognized roentgenographically; (2) necrosis—destructive process of the bodies and intervertebral discs occurring in the lumbar cervical and dorsal regions, in the order named. Kyphosis may result so the diagnosis from tuberculosis may be difficult. The third is Charcot spine, the result of late syphilis with cerebrospinal degeneration. This produces severe deformity with new bone formation, but causes little pain. This has rather a characteristic appearance.

Malignant diseases of the spine are uncommon. Primary sarcoma is occasionally seen, characterized by rapid destruction of the body of the vertebra, with lack of involvement in the discs. Carcinoma is always metastatic, secondary to this disease in some other region. When observed roentgenographically, the aspect

is rather characteristic, showing a diffused, mottled, destructive thinning of the bony structure. This is replaced by tumor mass, so the bodies do not collapse.

Other rare diseases occasionally involving the spine include, osteomyelitis, osteitis deformans (Paget's disease), osteitis fibrosa, hypernephroma, chloroma, progressive myositis ossificans, erosion from an aneurysm, and spondylitis following cerebrospinal meningitis, typhoid, etc., are noted, but they do not offer differential roentgenological signs.

INJURIES

Injuries to the spine, include fractures, dislocations and gun-shot wounds.

Statistics show that 60 per cent of spinal injuries are fracture-dislocations, 20 per cent fractures only, and 20 per cent dislocations alone. It is also stated that 50 per cent of spinal fractures are not diagnosed. This is largely due to the fact that the cord is not involved, the case being diagnosed as a sprain. More universal use of the x-ray will undoubtedly lower this large percentage. Fractures of the spine are classified according to the nature of the injury into direct or indirect, those from indirect violence predominating. In these the spine is forceably flexed, causing compression of the bodies, with tearing asunder of the arches and ligaments, while in direct violence the arches are compressed and the bodies separated. In either class the cord is well protected from injury owing to its position near the center of the spine. As stated by Jacobson, "It lies in neutral ground in respect to forces which might cause fracture." It is oftentimes surprising what little damage occurs to the cord in severe injury to the bony framework. In fracture-dislocation injuries from indirect violence the upper segment is usually driven forward on the lower, frequently with partial rotation and some lateral displacement of the body. The first lumbar vertebra suffers more often than any other, due to its location near the center of the spine and at the junction of

the fixed portion of the dorsal spine. Here the leverage would be greatest and this vertebra is slightly smaller than those below. As previously stated, only one-fifth of severe injuries produce dislocation alone. The vertebrae are snugly articulated and securely bound together with ligaments; hence, an injury producing a dislocation would rupture these ligaments and this amount of force usually produces a fracture dislocation. Ordinary strains or sprains do not displace the vertebrae. These bodies are not the nervous, jumpy migratory things some of our modern spineologists would have us believe. In the hundreds of spinal roentgenograms examined I have not seen a displaced vertebra unless caused by severe injury or disease.

Gun-shot wounds differ according to the necessity of removing the foreign

body. The x-ray is then in order. If the foreign body is not producing pressure symptoms or active infection then it is better to leave it alone. This is our conclusion after seeing a large number of these cases in our work with the Veterans' Bureau.

CONCLUSIONS

The roentgenogram is the only way of diagnosing anomalies, and the best single method for studying spinal curvatures or deformities. A few diseases show pathognomonic x-ray signs; in others the roentgenogram is a valuable adjunct in diagnosis.

All injuries of the spine, unless trivial, should be roentgenographed in both the anteroposterior and in the lateral projection.

ROENTGEN LOCALIZATION OF INTRATHORACIC STRUCTURES

WITH REPORT OF FINDINGS IN 19 CASES OF LUNG ABSCESS*

CLAYTON R. JOHNSON, M.D.

LOS ANGELES, CALIF.

STEREOSCOPY and examination of the chest in the lateral position, sometimes combined with lipiodol filling, are roentgen methods commonly used for the intrathoracic localization of normal or abnormal structures. In none of these can any exact information be obtained concerning the location of these structures with relation to anatomical landmarks on the bony thorax.

What I propose here is a simple method whereby the dimensions and location of any structure, whether normal or pathological, may be readily calculated. The method is based on the ordinary stereoscopic roentgenograms made for the diagnosis of suspected intrathoracic pathology.

TECHNIC FOR ROENTGENOGRAPHY

1. Set up the apparatus for stereoscopic roentgenograms of the chest in the upright position.

2. Center the target of the tube to the center of the plate changer with a target-film distance of 180 cm.

3. Arrange for vertical shift of 7.5 cm. each side of the center or a total shift of 15 cm.

4. Place the identification pad bearing the date in the upper left-hand corner of the plate changer. Place the identification pad bearing the patient's number in the upper right-hand corner of the plate changer.

5. Make stereoroentgenograms with suitable exposure during a single period of inspiration.

This set up is used in all examinations of the chest. The localization of any unusual structure may then be made a part of the first report.

TECHNIC FOR CALCULATION

1. Place the stereoroentgenograms in the stereoscope, and on one of the films place ink dots on the rib anteriorly and the

Abbreviations: Dur.—duration; Loc.—location; e.g. 7LP—7th rib, left posterior; FML—from midline; Conf.—confirmation.

rib posteriorly at points which lie in a horizontal line with the structure for localization.

2. Superimpose the two films in such a way that the shadows of the markers in the upper corners of the roentgenograms are exactly superimposed and fasten the films together with spring paper clips. Note if the right-hand edges of the films are exactly superimposed and parallel. If they are not, then draw a line marking the edge of the overlapping film. This procedure is to insure a parallel shift in marking the points for calculation.

3. Remove the paper clips and shift the films over one another in a longitudinal direction, keeping the right borders of the films or the border as marked in paragraph 2 parallel and superimposed, until the shadows of the anterior rib marked in paragraph 1 are exactly superimposed. With a needle perforate both films at the point marked in paragraph 1.

* Read before the regular monthly meeting of the Trudeau Society, Los Angeles, March 25, 1930.

4. In like manner superimpose the shadows of the posterior rib and perforate both films at point marked in paragraph 1.

FIG. 1. Case XVIII. Abscess cavity 3 cm. in diameter. Center 2 cm. posterior to point on upper border of right fourth rib, 8 cm. to right of midsternal line.

5. Superimpose the shadows of the structure for localization, still keeping the right hand borders of the films superimposed and parallel, and clip the films together.

6. Measure the distance in millimeters between the points marked on the anterior rib. This distance times 10 will be the depth of the structure as measured from the point selected on the rib. For example in Case XVIII, Figure 1, when the shadows of the abscess cavity are superimposed the distance between the points marked on the anterior rib is 2 mm. The product of 2 and 10 is 20 mm. Therefore the approximate center of the cavity is 20 mm. or 2 cm. from the point marked on the rib. In like manner the distance may be calculated from the point selected on the posterior rib.

7. Measure the distance in centimeters to the right or left of the midsternal line if the structure is located anteriorly, from

the midvertebral line if located posteriorly. The plane dimensions of the structure may be measured directly from the radiogram.

FIG. 2. Relationship of displacement of shadow of point to distance from film, according to formula of Buguet and Gascar. (See text.)

A representative report should then read as follows:

Case XVIII, Figure 1: There is an abscess cavity in the right lung. Its diameter is 3 cm. Its center is 2 cm. posterior to the upper border of the right fourth rib at a point 8 cm. from the midsternal line.

An abscess cavity is roughly spherical or ovoid in shape. Its shadow is cast by those rays tangent to its lateral surfaces. Its approximate center will then lie in the vertical plane of the margins which cast the shadow. The surface of the cavity nearest the chest wall will be closer to the chest wall than the center of the cavity by one-half the shortest diameter of the cavity. In the preceding instance, with a cavity 3 cm. in diameter with its center 2 cm. from the chest wall, the near point of the cavity should be within 0.5 cm. of the chest wall. In practice this has been proved to be approximately correct.

DISCUSSION OF THE METHOD

For all practical purposes, a roentgenogram of structures at a maximum distance

of 8 in. from the film taken with a target-film distance of 72 in. (180 cm.) will have a maximum distortion of 10 per cent. The

between their distances from their roentgenogram. For example, in Case XVIII a point on the right fourth rib anteriorly

FIG. 3. Case I. Abscess cavity in left lung. Size 3 cm. by 1.5 cm. Its center 2 cm. anterior to a point on the left seventh rib, 8 cm. to the left of the midvertebral line.

FIG. 4. Case II. Abscess cavity in right lung. Size 5 cm. x 2.5 cm. Center 2 cm. posterior to a point on right third rib, 10 cm. to right of midsternal line.

closer the object to the film the less the distortion. Therefore it is possible to measure directly from the film dimensions of length and breadth.

The shift of the shadow of the structure on stereoscopic roentgenograms determines its distance from the film at the time of the exposure according to the diagram, table and formula* of Figure 2. AF is the unknown distance of the object from its roentgenogram; 180 cm. is the target-film distance; 15 cm. is the shift of the target; xy can be measured directly when the stereoscopic roentgenograms are superimposed. By substituting varying values for xy from 0.1 to 2.0 cm., the values for AF were calculated as shown in the table.

For all practical purposes an increase in xy of 0.1 cm. causes an increase of AF of 1.0 cm. The vertical distance between the depths of any two points is the difference

* Formula of Buguet and Gascar, 1896.

has a shift in its shadow of 3.0 mm. (0.3 cm.). The margin of the abscess cavity has a shift in its shadow of 5.0 mm. (0.5 cm.). The difference between the shift of the rib and the shift of the cavity is 2 mm. Therefore, the margin of the cavity must be 20 mm. or 2.0 cm. from the rib. If we wish to be more exact, the values of AF may be found in the table. In this particular instance the depth of the cavity would be the difference between 5.8 cm. and 3.4 cm. or 2.4 cm.

To further simplify the procedure one needs simply to superimpose the shadows of the structure and measure the shift in the shadow of the adjacent rib. This distance in millimeters multiplied by 10 will be the approximate depth of the structure.

REPORT OF FINDINGS IN 19 CASES OF SIMPLE LUNG ABSCESS

During the past year this system of

localization has been used in 19 cases of simple lung abscess. Seven of the cases were treated surgically by Dr. H. E. of the lower lobe may lie between the chest wall and the abscess cavity. This occurred in Case xiv.

FIG. 5. Case vi. Abscess cavity in left lung. Size 2 cm. x 2.5 cm. Center 2 cm. anterior to point on left eighth rib, 6 cm. to left of midvertebral line.

FIG. 6. Odd-shaped bullet in lower left thorax. Length 3.5 cm. Location 7 cm. posterior to lower border of fourth rib, 10 cm. anterior to lower border of eighth rib, and 3 cm. to midline of sixth rib in midaxillary line.

Schiffbauer, Senior Attending Surgeon on the Chest Surgical Service at the Los Angeles General Hospital. The exact location of the abscess cavity in all of these cases was successfully calculated before operation. The location of four more were confirmed by autopsy. The accompanying table (Fig. 3) gives a summary of the findings in all cases.

On reviewing these findings it should be noted that in the majority of instances the cavity was subpleural. It was located either anteriorly or posteriorly in the thorax. In most cases the cavity was accessible to surgical drainage. We have encountered one type in which surgical approach was somewhat complicated. This type is that in which the cavity occurs along the distribution of the posterior upper lobe bronchus and lies near the interlobar fissure. In this instance the upper portion

CONCLUSIONS

Intrathoracic localization may be made a comparatively simple procedure readily applied by the experienced roentgenologist. It is applicable to all those instances where accurate localization of intrathoracic structures may be of value in diagnosis or treatment.

A report of a roentgen examination of the chest is not complete without giving exact information as to size and location of any unusual structure.

This method has been found particularly applicable to the localization of simple non-tuberculous lung abscess cavities, to the localization of foreign bodies within the thorax and to the localization of certain tuberculous lesions.

RADIATION THERAPY FOR BENIGN UTERINE HEMORRHAGE*

LEWIS J. FRIEDMAN, M.D.

NEW YORK

THE title of this paper has been chosen significantly, after the elimination of conditions not included in this category.

While the cause of menorrhagia or metrorrhagia was, as a rule, recognized to be a fibromyoma, a number of bleeding patients presented a rather obscure etiology. Six out of the number reviewed were married women between the ages of twenty-five and thirty-six. The diagnosis of fibrosis uteri was suggested tentatively, although the author doubted that this etiology applied to all of this series.

Schmitz¹ presented a logical classification of the types of benign uterine hemorrhages as follows: (a) hyperemia; (b) polymenorrhea; (c) metrorrhagia. The difficulty of differentiating among the three types, however, is evident.

The diagnostic curettage so much heralded by gynecologists, while a necessary prerequisite to radiation therapy, is not always the possible procedure in private practice. Most patients consider this a surgical risk and refuse to submit to it.

Stacy and Mussey² limit their curettement to patients more than forty years of age. At any rate, its importance prior to the insertion of radium is obvious.

Thirty-four patients who gave definite physical signs of tumor varied between the ages of thirty and fifty-five. The number of masses felt in the pelvis varied from one small nodule in some, to several large tumors in a few patients. One patient in this series in whom the result was only palliative, had an enormously enlarged uterus, and although the contraindications on account of the doubtful result were explained to the patient, she absolutely refused an operation. She returned recently after a period of six months of freedom from symptoms, with recurrent bleeding.

Another patient in whom the result was poor, proved eventually to have had a benign intraligamentous tumor.

The indications and contraindications were naturally considered. The indications in the majority of patients of this series corresponded with those promulgated by J. C. Mason:³ (1) past normal age of menopause; (2) history of menorrhagia; (3) tumor less than 15 cm. in diameter; (4) fibrous type uterus; (5) essential uterine hemorrhage; (6) young patients who refuse operation; (7) bad surgical risks.

The chief objective symptom in the author's series was hemorrhage. Subjectively, backache and "bearing-down pain" were the complaints with larger tumors.

The hemoglobin estimation and blood count in a number of patients were always below normal, while in several, the hemoglobin was less than 70 per cent and the erythrocytes fewer than 3,500,000. The hematopoietic regeneration invariably occurred with the cessation of the bleeding.

Since Crile's⁴ utterance in 1924 that "in the child-bearing period, radium and x-rays should be used only in the treatment of cancer of the cervix, since surgery relieves practically all cases and preserves the ovarian balance," many investigators, both radiologists and gynecologists, have amply demonstrated the possibility of preserving the conceptive powers of the adnexa exposed to radiation.

While the regional classification was as a rule attempted, the uncertainty of accuracy readily suggests itself, in view of the fact that a mass felt subserously may be wholly intramural where most of the fibromyomata originate. Furthermore, the presence of a subserous mass does not eliminate the possibility of a submucous nodule. Although the clinical results are

* Submitted for publication April 2, 1930.]

uniformly good, the regional classification is also important in indicating the proper type of emanator of radiant energy. The *submucous* fibromyomata or *pedunculated* tumors are likely to ulcerate on account of the too intense *radium* bombardment. Better results may be expected with x-rays, although pedunculated tumors should be removed *surgically*. The large *subserous* fibromyoma does not react so well with *radium*. The reason for this may be explained as follows: the radium applicator being inserted in the uterus is a goodly distance from the mass, especially if the latter is centripetally situated. Furthermore, the intensity of radiation varies as the square of the distance, hence an insufficient amount of rays reaches the subserous neoplasm. However, radium is the applicator of choice in young women suffering from idiopathic uterine hemorrhage because the dose to be applied can be controlled more accurately. Clinical experience has taught us that 250 to 800 milligram or millicurie hours will produce a temporary amenorrhea which may last two to six months. The castration dose is two to three times greater.

In the author's series radium was applied eight times with invariably good results. In only 1 of the 6 (aged thirty-five) hemorrhage cases a permanent amenorrhea was produced with the x-rays. In another of this series, the patient became pregnant some months later. Phahler⁵ cited his unusual experience with a patient in whom a uterine fibroid disappeared with irradiation without a temporary amenorrhea. Subsequently she gave birth to two healthy children.

Although the author has by choice employed the x-rays, he did not hesitate to use radium where indicated and the patient's financial status permitted it. The cost of radium and the necessary hospitalization are an item which is a serious consideration to the patient of moderate means.

At present the author employs deep penetrating x-rays of 180 kv. peak and filtered by 0.5 mm. of copper and 1.0 mm.

of aluminum. The target to skin distance is 50 cm. Fractional exposures twice weekly are given until a full erythema dose is administered. This is usually completed within three weeks, depending upon the urgency. Other series are repeated within six weeks as indicated. Some tanning and an occasional bronzing of the skin occur.

In most patients radiation is given through one portal, 15 cm. in diameter in the suprapubic region, and another through the sacral region. In some patients with multiple tumors, irradiation is done through a portal on either side of the median abdominal raphe.

The irradiation with radium involves hospitalization of the patient, meticulous preparation of the genitalia and the patient as for major surgery; the properly prepared radium salt or emanation is then inserted into the uterine cavity. The dose given varies from 250 to 2000 mg. hours or its equivalent in millicuries.

RÉSUMÉ

1. Radiation therapy is an excellent remedy for benign uterine hemorrhage due to fibromyomata or the type classed as idiopathic, with few exceptions.
2. X-ray therapy is superior for all types of fibromyomata and it is also less expensive for the patient of moderate means.
3. Radium is an excellent remedy in selected cases, especially in young women, but more expensive.
4. Finally, radiation therapy is a potent but a dangerous remedy in the hands of the tyro. Improper irradiation unwarrantably discredits a fine therapeutic agent.

A PRACTICAL X-RAY SERIALOGRAPH*

A. I. ARNESON, M.D.

STARBUCK, MINN.

THE writer wishes to present herewith an x-ray accessory for making serial roentgenograms, and a method of

lastly the backing of wood and bakelite to give it strength and rigidity. Through an opening near the bottom of one side

FIG. 1.

suspending it in a convenient manner in a permanent installation alongside the fluoroscope.

The tunnel is made to accommodate one regular 10 x 12 in. cassette, and produces on this film six separate roentgenograms, each taken a short interval after the preceding one. This tunnel is 20 x 24 in. outside measurement and weighs about 32 lb. It is made up in the regular manner with a sheet of 1 mm. of aluminum next to the patient, then a sheet of lead 2 mm. thick with the 4 x 5 in. aperture in its center; then the proper space for the cassette, and

are inserted two strips of wood 4 in. wide and 22 in. long.

In operation, the tunnel is pulled along on its trolley and then lowered between the patient and the fluoroscopic screen; the portion desired is then centered in the 4 x 5 in. opening, and the patient by grasping the edges of tunnel and fluoroscopic screen holds all tightly against his abdomen. The 10 x 12 in. cassette is then inserted in the space at top and brought over to position "A" and an exposure made, then the cassette is moved over to position "B" and the second exposure

* Submitted for publication May 23, 1930.

made. The upper of the two wood strips is then pulled out, allowing the cassette to drop down 4 in., and two more exposures are made in a similar manner, and then the bottom board is pulled out and the last two exposures made. In this way six exposures are quickly made, each 4 x 5 in., on one 10 x 12 in. film, and all six are right side up instead of two right and two upside down as with the original model on which this idea is an improvement.

The trolley system consists of 1 in. gas pipe fastened by floor plates to joists in the ceiling by lag bolts. This is constructed and placed in such a manner that no portion comes nearer to the overhead high tension wires than the original construction of the fluoroscope involves, passing entirely under and around the wires in cases where they approach the fluoroscope from the front. The trolley wheels are

turned to fit the pipe and by bracing as shown a very light yet rigid construction is achieved. The counterbalancing system consists of the nickel-plated tubular standard of an old x-ray tube stand and its original weight sliding within it. The tunnel and weight are easily equalized by melting out or adding to the required amount of lead.

When not in use, the entire apparatus is easily shoved over to one side on the trolley where it remains always ready for instantaneous use.

For handling the cassettes when within the tunnel, one may bore a hole near the corners at one end into which are fitted the hooked ends of a wire bail. This does not injure the cassette, is more convenient than a pan, and does not alter the cassette so as to prevent its use in the ordinary manner.

THE ACHIEVEMENTS OF UTEROSALPINGOGRAPHY*

JOSEPH KALDOR, M.D.

BROOKLYN, N. Y.

IN THE year 1914 Dartiques and Dimier by their "Radiographie Periuterine et Endouterine" introduced for the first time the new method of uterosalpingography. Independently, Cary of Brooklyn and Rubin of New York advanced the identical method in 1914. Regarding priority, the credit can be given to Cary and Rubin as Dartiques and Dimier did not give their results publicity until 1916.

Since then uterosalpingography, or as some prefer to call it hysterosalpingography, has proved almost indispensable in certain phases of diagnostic gynecology and obstetrics, and has revealed new facts in the anatomy and physiology of the female genital organs.

The success of uterosalpingography depended entirely upon the use of a proper medium which had not only to give a strong x-ray shadow, but at the same time avoid any harmful action on the tissues. Dartiques and Dimier used 7 to 8 c.c. of a 10 per cent collargol solution for the visualization of the uterus and adnexa. Later on argyrol and bismuth paste were used by others. But these solutions did not give satisfactory x-ray shadows and furthermore caused untoward effects, such as peritonitis, abscess formation and adhesions. It was due to the failure to find a proper agent that uterosalpingography was not generally applied as a diagnostic method until about 1923.

In the interim Zimmerman used umbrenal; but this had a very bad effect on the mucous membrane of the tube and on the peritoneum of the Douglas pouch and therefore failed to gain general acceptance.

In the search for satisfactory contrast material many men deserve credit. For the sake of brevity we shall only mention

the following few: Mocquot, Tussau, Schneider, Jarochka, Arnstam, Serdukoff, Carelli, Randall, Kennedy, rather an international galaxy and showing the study to be of widespread interest.

Among the agents most widely used were bromnatrium, collargol, argyrol, sodium iodide, iodakol, iodipin and lipiodol. At first the solutions containing iodine were used with care and trepidation because of the fear that they might have a destructive action on the tubal epithelium or show toxic effects. But experience showed that these considerations were not warranted.

Among the iodized oils, iodipin and lipiodol gained foremost reputation due to their merits and recently the latter has almost unanimously been given first choice. Iodipin was first used by Winternitz. One cubic centimeter of iodipin contains 0.51 gm. iodine in an organic combination. In the opinion of Zimmerman and Nahm-macher it is harmless to the ciliated epithelium of tubal mucosa and its only drawback is its heavy viscosity. But Dyroff claims it to be decidedly harmful because it causes oily deposits of long duration, fibrinous exudates and adhesions.

Lipiodol was used by Lafay in 1901 for therapeutic purposes only and as contrast material in 1925 by Sicard and Forestier. One cubic centimeter of lipiodol contains 0.54 grams of iodine in a vegetable oil combination and is tolerated by the organs with which it comes in contact as the least irritant of all known solutions and gives the sharpest x-ray shadow.

Preliminary to uterosalpingography the patient should receive a bowel evacuant the night before, and be put on the x-ray table with an empty bladder. In order to gain better visualization, Saint Portret

* From the Department of Gynecology of the United Israel Zion Hospital, Brooklyn, N. Y.
Submitted for publication November 11, 1929.

and Dimier recommend rectal and vesical insufflation; Heuser, Carelli, O'Campo and Arens favor a pneumoperitoneum in conjunction with the uterosalingography, but it may be safely said that no special advantages can be gained by the use of this combined procedure.

The instrumentarium is simple and easy to handle. It consists of a vaginal speculum, a tenaculum, a syringe with long nozzle and the contrast material. Some prefer to introduce the contrast material by means of a catheter, others use the rigid nozzle. Some have a special pressure-reading attachment on their syringe in order to control the applied pressure, as in the "Schneider-Beclere Hysteromanometre." Others use a different sized nozzle, still others apply a rubber stopper on the nozzle to prevent the backflow of the injected solution, and some use both. Temesvary attaches his syringe to the tenaculum in such manner that the nozzle is held firmly in the cervix and at the same time the cervix is pulled down. In this way the injection can be managed with one hand. An inexpensive and yet very efficient one is a modified Ultzman-Record syringe.

The appropriate time to do uterosalingography is midtime between menses. Shortly before or after menstruation the swelling of the endometrium may occlude the uterine ostia of the tubes and prevent the contrast material from entering into them.

The instruments used must be sterile and the procedure executed under strict precautions of asepsis. The technic is as follows:

The patient is put on the x-ray table, recumbent, or as some prefer, in the stone-cutting or Trendelenburg position. The vaginal speculum is inserted, the vagina and cervix thoroughly disinfected and after the cervix is grasped, the nozzle of the syringe is inserted into the canal and the lipiodol injected slowly, about 1 c.c. per minute. Those who use the manometer, control the applied pressure by the reading; but their recommendations vary from 60 to

200 mm. Hg pressure, sufficient proof that this precaution is unnecessary. The best manometer after all is the hand, which will recognize readily any undue resistance and will not assert itself against it. As to the quantity of the injected fluid, no definite ruling can be set: it varies with the individual case.

Some precede the radiography by fluoroscopy. Fluoroscopy will give information about the degree of filling and the contractions of the uterus; but as to finer details, only the radiography is satisfactory.

If only information about the uterus is sought for, the radiography may follow immediately upon the injection; but if the tubes have to show up on the plate, it is safer to wait from eight to ten minutes. A second and third film should be exposed one hour and three hours after the first picture, but without repeated injections. These radiographs are made for the sake of control and for further information about the localization of the contrast matter.

In case the tubes are patent and the lipiodol reaches the abdominal cavity, it will undergo absorption there. As to the length of time that this will require, the opinions vary: some believe a few days, others claim that it takes weeks or months. When found at any later date in the abdomen it never seems to have caused any irritation of the peritoneum and in Schober's examinations these lipiodol rests were always sterile.

Gregoire and Darbois employ lumbar anesthesia but this is not necessary because uterosalingography hardly ever causes any pain beyond discomfort of short duration. In fact it is tolerated much better than gas insufflation.

In regard to the anatomy and physiology of the female genital organs, uterosalingography has revealed the following facts:

The position of the uterus is rarely in the midline of the pelvis; but I myself am inclined to believe that this deviation from the pelvic axis is due to the traction exerted upon the cervix during manipulation. The cavity of the normal uterus is always

triangular. This triangular shadow varies in size on the x-ray film and is dependent on the position and version of the uterus. The more stretched the uterus is, the higher will we find this triangle to be: retroversion without retroflexion enlarges the shadow cast upon the film, and the more pronounced the retroflexion, the shorter it will measure.

At the fundus from cornu to cornu, this shadow measures from 3.6 to 4.3 cm. in normal uteri. From fundus to cervix, the measurement varies; but if it is over 4 to 4.5 cm., it is in direct ratio to the retroversion.

The uterine cavity fills up with 3 to 10 c.c. of lipiodol in normal conditions, dependent on the tonicity of the musculature and the applied pressure.

Reinberg and Arnstam observed under the fluoroscope that after filling the uterus by way of a catheter, in some cases part of the contrast material was at once expelled back into the vagina, and part of it was forced through the tubes into the abdomen. From this they concluded that there is not only an expelling muscular action of the uterus, but also a peristalsis on the tubes from cornua to fimbriated end. It is known that the normal peristalsis is from fimbriated end to cornua; but that there is also an antiperistalsis is proved by Henkel, who injected only 0.5 c.c. of iodipin into the uterus, placed the patient in Trendelenburg position, and on radiography half an hour later, found the iodipin in the tubes. Temesvary and Mikulicz believe that antiperistalsis takes place only if the backflow of the contrast material meets obstruction in the cervix. They introduced into the uterine cavity a lipiodol saturated applicator and upon withdrawing this quickly found that the expulsion of the lipiodol took place towards the vagina. However, if they left it in place so as to occlude the internal os, the lipiodol was observed to ascend into the tubes. On the x-ray film the peristalsis of the tubes can be recognized by the fact that the contrast material does not give a continuous

shadow, but that it is broken up into fractions.

In 1926 Heuser from his observations concluded that there is a salpingouterine sphincter action and later Romcke proved this physiological supposition by his anatomical findings. This sphincter is situated about the middle of the intramural section of the tube. Its presence was proved by Schneider and Eisler on the basis of manometer readings. On the removed organ this sphincter is tetanic enough so as not to allow the filling of the tubes from the cervix, whereas in the living organ, the same specimen showed easy permeability. In the living, due to some unknown reason, the sphincter may be in a spastic stage and, in order to differentiate between such state and an organic, permanent obstruction at the sphincter's site, atropine should be given to the patient ten minutes prior to the injection of the lipiodol which will bring about a relaxation if the closure is only functional.

The tube is capable of elongating to an unbelievable length, as is seen in cases of prolapsed uteri where the cervix protrudes beyond the labia and the tubes remain in the pelvis and reach far up.

Further facts revealed by uterosalpingography and reported by Susaki are:

Thirty days after birth the uterus is still not normal in size. The cervix assumes its prenatal form in multiparas much sooner than in primiparas and in the early puerperium we find the uterus mostly in an anteversion and anteversion. In the late puerperium it is mostly in retroversion.

Besides these ascertained anatomical and physiological factors, uterosalpingography offers more valuable service in diagnosis. Its foremost application is in cases of sterility. According to Jarcho, "it not only supplements but frequently supplants insufflation of gas." If the Rubin test shows the tubes to be patent, reasonable doubt can be maintained whether one or both tubes are permeable, and if the manometer reading indicates obstruction, information as to the site of the trouble is

still missing. These drawbacks are eliminated by the properly executed uterosalingography. It gives us information about both tubes and by localizing the site of lesion will indicate operative possibilities for the cure of sterility. Furthermore the iodized oil may have definite therapeutic advantages in subacute and chronic conditions of the Fallopian tubes.

If the tubes are patent we will find on the x-ray film shadows of droplets and clots of lipiodol in the free abdominal or pelvic cavity. If the tube shows up as possessing a blunt end, like a club, one must not conclude from this appearance that the fimbriated end is closed; there is a possibility that the lipiodol is filming it and gives the impression of obstruction. In such doubtful condition it is advisable to follow up with another radiograph an hour or two later, to search for the only conclusive signs of tubal patency, i.e. droplets and clots of lipiodol or to repeat the whole procedure by applying more pressure during the injection.

Henkels and Rouves base their diagnosis of ovarian tumor on the fact that the tubes appear extraordinarily elongated. The diagnostic point of Rosenblatt and Kesz is, that the surfaces of these growths become covered with lipiodol and show up as some part of a spherical body. According to others the diagnosis is made on the basis of negative x-ray findings, i.e., the tubes and uterus are normal but the clinical findings point to some growth.

In differentiation of myomas it is fairly satisfactorily established that in submucous myomas we will find a filling defect in a deformed uterus. In intramural myomas, instead of the triangular uterine shadow, we will find an asymmetrical and deformed one. We are to note that a submucous myoma of the posterior wall will show up only if the film is exposed in a lateral position. Incidentally I wish to mention that Samuel noticed, upon using a 25-30 per cent sodium bromide solution as contrast material in the visualization of myomatous uteri, that as a sequel these

myomas decreased essentially in size and that the menorrhagia diminished. It is explained by the dehydrating action of this highly concentrated and hygroscopic salt solution.

The diagnostic signs of a four to six weeks' pregnancy are according to Popovitch the following:

1. Form changes, i.e. the uterus is larger, symmetrical and atonic.

2. Under the fluoroscope irregular contractions are observed.

3. These contractions become regular, almost rhythmical, under the influence of pituitrin.

4. A filling defect is seen in some part of the uterus corresponding to the location of the ovum. This defect is always convex, broader than long, and the edges are never clean-cut, in differentiation from a submucous myoma.

In missed or incomplete abortion all these signs may be detected except the last mentioned one. The filling defect is not present and instead, according to the fact that the contrast material has mixed rather unevenly between the different and loose parts of the products of conception, the picture is that of a spherical bag filled with different sized and shaped fragments of lipiodol shadows.

In spite of the fact that many men, as Carlos Heuser, Dyroff and Arnstam have applied uterosalingography to determine a question of pregnancy and have claimed that it is harmless to the mother and that it does not bring about an abortion, Joachimovitz found that iodine absorption takes place readily in pregnant women, causing severe acne eruption. Many others would not apply this diagnostic method for fear of harming the fetus. We are inclined to take sides with the latter and esteem pregnancy as one of the contraindications to uterosalingography.

In the diagnosis of tubal pregnancy the following points may be utilized:

1. The gravid tube either does not fill with contrast material at all or fills up only very slowly and to an insufficient degree.

2. The isthmic portion of the tube is larger than usual.

3. In the pregnant tube the distal end of the contrast material shadow stops suddenly and is concave towards the fimbriated end. This phenomenon is explained by the fact that both the lipiodol and the tubal contents as a whole are elastic bodies and on the surface of their contact the tubal contents will resist the pressure of the lipiodol, causing it to stop in a concave line.

4. Sometimes the gravidity filling defect can be seen in the tube.

5. The previously mentioned signs of pregnancy are present on the uterus itself.

It must be remembered that in tubal pregnancy uterosalingography involves some danger through the possibility of causing a rupture.

Other uses of this method are in the diagnoses of malformations, in the differential diagnosis between uterine and adnexal tumors and in certain postoperative follow-up cases.

As contraindications, the following are generally accepted: fever, gonorrhea, preg-

nancy, malignancy and inflammations, although Cotte and Bertrand apply it even in such cases for therapeutic purposes.

Before closing this review I want to call attention to a perversion to which uterosalingography has led some men. They have injected 15 to 20 c.c. of lipiodol by way of a Douglas puncture in order to reveal diagnostic facts in cases of tumors and adhesions. It is needless to say how hazardous and unnecessary is such an undertaking.

DISPLACEMENTS OF THE UTERUS*

W. P. TEW, M.B., F.R.C.S.

LONDON, CANADA

ONE must at least briefly review the normal supports of the uterus before entering upon the discussion of the subject of uterine displacements. Usually we find that the displacements follow upon damaged or diseased supports. Under normal conditions the tone of the supportive structures is sufficient to maintain the uterus in good position.

The uterine supports are loosely arranged in order that the uterus may undergo considerable mobility. The pregnant uterus gradually changes its position from the beginning to the end of pregnancy. This marked alteration in position and size of the uterus could only occur with loosely arranged attachments. The degree of fullness of the bladder alters the position of the uterus. The normal degree of uterine antifixion can only occur when the bladder is empty. A distended lower bowel tends to push the cervix forwards and this will carry the uterus backwards. Physiologically the uterus will be in its most normal position when the bladder and rectum are empty or nearly so.

The peritoneal ligaments are morphologically of the nature of a mesentery. They carry the nerves and blood vessels to the organ and offer resistance only to gross displacements, leaving the uterus a wide range of mobility. The mobility of these attachments allows of the uterus being drawn forwards and upwards to or through the abdominal wound during operation. These ligaments therefore are not normally true supports of the uterus. The round ligaments compare morphologically to the gubernaculum testis of the male. The function of this structure is developmental only and the portion which becomes the round ligament may be regarded as a vestigial structure which serves no definite purpose in the adult.

Its normal laxity and its marked variation in size seem to obviously mean that it has but little to do with holding the uterus in its normal position. These ligaments are serviceable however to the surgeon when he wishes to use them as supportive structures.

The uterus is held in position mainly by the fascial and muscular structures which also serve to close over the lower part of the pelvis. These structures may be conveniently arranged into two groups, (a) the superficial and (b) the deep. The superficial or sphincter group is made up of: the superficial sphincter ani; the transverse perinei; and the sphincter vaginae muscles; along with the superficial and deep layers of perineal fascia. The deep group constitutes the pelvic diaphragm. It is made up of the levator ani and the coccygei muscles, along with the visceral layer of pelvic fascia. This pelvic floor is weakened by the passage through it of the vagina and the urethra. This element is however partly counter-balanced by the fact that the vagina and urethra are attached to the sloping sides of the pelvic floor by a layer of pelvic fascia which is continuous with the general pelvic fascia and attached to the pelvic wall at the "white line." Another assisting factor is that the uterine vessels bring with them an investment of fibrous tissue. The so-called transverse cervical ligament adds further support. The definite support offered by this fibrous tissue around the lower uterine segment and upper part of cervix is appreciated in doing a vaginal hysterectomy. It is difficult to pull the cervix down to a lower level until these lateral attachments have been severed. When the uterine vessels and transverse cervical attachments have been severed the cervix can be readily pulled downwards,

* Read before The American Association of Obstetricians, Gynecologists and Abdominal Surgeons, Memphis, Tenn., Sept., 1929.

as the upper peritoneal attachments allow so much mobility that the uterus may be readily delivered and freed from those attachments. The uterus is therefore maintained at its normal level chiefly by the following supports: (1) pelvic diaphragm, (2) transverse fascial and fibrous bands, (3) fibrous sheaths of blood vessels.

The displacements of the uterus may be considered as follows:

(a) Forward displacement: anteversion, antelexion.

(b) Backward displacement: retroversion, retroflexion.

(c) Downward displacement: prolapse.

(d) Inversion: turning inside out.

Forward Displacement: Anteversion is the normal position of the uterus. The degree of anteversion will vary with the filling and emptying of the bladder.

Antelexion may be congenital or acquired. The congenital variety is rare. It is often associated with some degree of under development of the uterus. The functioning of the ovary in these cases may not be normal. The acquired type may result from a uretosacral cellulitis, or from certain pelvic adhesions. The uterine angle is reduced below a right angle and a consequent abrupt bend in the curve of the uterocervical canal. The diagnosis is made by the finger on bimanual examination or by use of the uterine sound. All such cases are not necessarily pathological. The two main symptoms of pathological antelexion are spasmodic dysmenorrhea and sterility. In the congenital variety the deficient development of the organ may account for the symptoms and not the acuteness of the angle. The treatment of the congenital type is at times discouraging. In a few cases pregnancy ensues and the condition is cured. Dilatation of the cervix usually gives but temporary relief. Electrical stimulation has proved discouraging. Stem pessaries help temporarily. In the chronic type of forward displacement the treatment is that adopted for pelvic inflammation.

Backward Displacement: The uterus may

be displaced considerably backwards without in anyway interfering with its normal function. Every case of backward displacement is not pathological and does not require treatment. The condition is often incidentally discovered. The backward displaced uterus may or may not interfere with insemination. Many women with backward displaced uteri conceive and go through a normal pregnancy. The backward displaced uterus may encounter some difficulty in properly emptying itself during a menstrual period. A uterus with good muscular tone may empty itself without difficulties against gravity. In certain cases muscular spasms result with pain or dysmenorrhea. The retroverted uterus may cause varicose veins in the pampiniform plexus of the broad ligament. This is due to the broad ligament being folded backwards over the edges of the uterosacral ligaments. This causes stasis and engorgement of those veins. Varicose veins of the broad ligament can cause a dragging pain in the lower lumbar region. This becomes more marked premenstrually and menstrually due to the increase in the pelvic blood supply at that time.

Retroversion has often been found in the newborn baby. This congenital type may remain retroverted or may later in life be found corrected. At times one finds a patient with a retroversion today and in a few days' time the uterus is found in quite good position. Such uteri as these seem to have a marked degree of mobility and they doubtless change their positions many times during the patient's life, without causing symptoms.

The first degree of backward displacement is that in which the uterus is lying much in the same position as it is when being pushed backwards by a full bladder. This is spoken of as a retroposed uterus. The further degrees of retroversion will vary from that of a retroposed uterus to the uterus which is forward lying on the floor of the pouch of Douglas. We may therefore for clinical purposes consider

retroversion in three stages or degrees. The first stage being the retroposed uterus, the third stage being the extreme degree when the uterus is lying on the floor of the pouch of Douglas. The second stage refers to the position of the uterus when it is lying midway between these two positions.

The causes of acquired backward displacement may be grouped as follows: (a) relaxation of the uterine supports, (b) abnormal size and weight of uterus, (c) abnormal intra-abdominal pressure, (d) pelvic adhesions. The relaxation of the uterine supports along with an increase in size and weight of the uterus are the two factors which occur together post partum. It is therefore obvious why backward displacement is rather frequently found during this period of the maternity patient's convalescence. Backward displacements occurring at that time are usually amenable to simple treatment if such is instituted at the proper time. Doubtless many of these acute puerperal displacements do return to normal, yet many of them become chronic backward displacements and later give rise to symptoms.

Many backward displacements remain as simple backward displacements and symptomless. Others are complicated and are accompanied with symptoms. The most common complication is descent. This means that the displacement is accompanied with a certain degree of descent of the whole organ. Another complication is prolapse of the ovaries. Often one or both ovaries will be found lying on the floor of the pouch of Douglas. Pelvic inflammation is usually an associated condition and not a complication. This condition requires operative treatment for correction of the retroversion. A uterine fibroid is also an associated condition rather than a definite complication of the displacement.

The symptoms of backward displacement vary considerably. As stated above, many backward displacements do not cause symptoms. The usual symptoms are

(a) pain in the sacral region and the lower abdomen, (b) menorrhagia, (c) dysmenorrhea, (d) leucorrhea, (e) sterility, (f) dyspareunia. These same symptoms are often found from other causes than backward displacements. The pain with backward displacement is not acute. It is usually in the form of a backache or a dragging sensation in the sacral region and in the lower abdomen. The pain is more marked when the ovaries are prolapsed. The menorrhagia may be the result of the accompanying endometritis. Dysmenorrhea is the result of the congestion along with the abnormal direction of the uterine canal. Sterility may only occur in a few cases of backward displacement. Urinary incontinence and bladder irritability if present are *not* due to the backward displacement.

The treatment of backward displacement of the uterus will vary somewhat according to the individual case. The treatment may however be conducted somewhat as follows: (1) In young unmarried women and in women who are long past the climacteric, if the case is uncomplicated, treatment is not required. (2) In sterile married women the displacement may be corrected even if no pelvic symptoms are present. (3) Cases occurring in married women in whom the ovaries are prolapsed usually require treatment. (4) Puerperal retroversions should always be corrected.

The actual treatment is essentially one of two forms: (a) pessary treatment, (b) operative treatment. Pessary treatment gives the best results in puerperal retroversions. In practically all other cases the pessary gives only temporary relief. The prolonged use of a pessary is objectionable, since it is difficult to keep clean and it may also cause ulceration. The pessary seldom ever cures a retrodisplacement except the puerperal cases. An operation suitably planned involves but little surgical risk and almost invariably presents a recurrence. A pessary used for puerperal retroversion should be inserted

reasonably early. It gives best results if used not later than the sixth or eighth week. A Smith or Hodge pessary is the one usually used. The patient takes a daily douche of a quart of warm water containing a teaspoonful of sodium bicarbonate. The pessary should be removed, cleaned and reinserted. At the end of about three or four months the pessary is removed and the patient goes one month without it. She then reports again for an examination. If the uterus is again out of position, the pessary may be tried for another month. At the end of this time it should remain in proper position without the pessary; if not, an operation is advised. Before attempting to replace a retrodisplaced uterus one should make sure that the lower bowel has been thoroughly emptied; also the bladder. In certain cases one may find it necessary to anesthetize the patient. Generally speaking this is not at all necessary.

The operation of choice for backward displacement is intraperitoneal shortening of the round ligaments, known as Gilliam's operation. This operation leaves the most normal uterovesical pouch. It also has the distinct advantage of not leaving any intra-abdominal structure around which the bowel may become entangled. One other distinct advantage is that if a pregnancy should follow it allows of practically normal and free mobility of the uterus upwards during its development. The uterus should *never* be fastened to the abdominal wall during the child-bearing period.

Prolapse is a complex condition which may involve several pelvic structures. There are five clinical varieties of prolapse: (a) Prolapse of the anterior vaginal wall (cystocele); (b) prolapse posterior vaginal wall; (c) prolapse of the anterior and posterior vaginal wall (cystocele and rectocele); (d) prolapse of the anterior vaginal wall and uterus; (e) complete prolapse of the uterus with inversion of the vagina (procidentia). Hypertrophic elongation of the cervix is a different condition and will not be considered here.

It is therefore clear that prolapse is not a displacement of the uterus alone, but usually the vaginal walls are involved in the descent as well as the uterus. In advanced cases we find that the bladder, rectum, fallopian tubes and ovaries, the broad ligaments, and even coils of intestine and omentum may form part of the prolapse.

Prolapse is really a hernia. It consists of a protrusion of the pelvic and abdominal contents through an aperture in the supporting structures. The coverings of the hernial sac are the vaginal walls and peritoneum. The hernial aperture is formed internally by the interval between the levator ani muscles and externally by the ostium vaginae.

Prolapse is much more common in multiparous patients than in nulliparous patients. Mechanical deliveries is common history. Once the condition has begun it may be aggravated by increased intra-abdominal pressure, e.g. tumors, chronic cough and laborious occupations. Constipation and straining will also aggravate the condition. Prolapse of the uterus may be considered to occur in three degrees. The first degree involves descent of the uterus to a lower level than normal; but the cervix does not protrude at the vulva; it may or may not be accompanied with retrodisplacement. The second degree involves descent of the uterus still further until the cervix protrudes at the vulva and it is always accomplished with retrodisplacement of the uterus. In the third degree or procidentia, the whole uterus is expelled through the vulva, and the vagina is more or less completely inverted.

In long standing cases of second and third degree prolapse, certain secondary changes occur. The anterior vaginal wall loses its transverse folds and becomes smooth and looks more like a skin surface. The vaginal walls become thickened, hard and rigid. Ulceration is not uncommon in long standing cases, due to defective circulation, chronic irritation and friction. Infection may spread deeply, causing a

local peritonitis and the promotion of adhesions.

The condition of the perineal body is of importance in connection with prolapse. Three degrees of perineal laceration are usually described. The first degree involves half of the perineal body. The second degree extends up to, but does not include the sphincter ani muscle. In the third degree the sphincter ani has been severed, the anus is wholly or partly incompetent, and a portion of the rectal mucosa often protrudes. In rare cases perineal damage may not be found, but usually there is some degree of perineal. A partial or complete loss of tone of the perineal structures will predispose prolapse and incompetence is a distressing complication of prolapse.

Cystocele means a protrusion of the anterior vaginal wall, along with the base of the bladder and the urethra. The vaginal wall becomes stretched and smooth. The protrusion begins at the lowest part of the anterior vaginal wall and gradually comes to involve the upper or posterior section, finally pulling downwards on the cervix. The hernia of the bladder has occurred between the two pubococcygei muscles. Overstretching or tearing of these muscle fibers predisposes to cystocele. Commonly these patients have bladder friction disturbance, e.g. dribbling of urine when they laugh, cough or sneeze.

Rectocele is a protrusion of the lower part of the posterior vaginal wall which has carried with it a corresponding portion of the anterior rectal wall. This is the rarest of all the forms of prolapse. In procidentia the posterior vaginal wall usually separates itself from the rectal wall, so that the rectum does not actually take part in the prolapse. The loose arrangement of the cellular tissue between the vaginal and rectal walls allows of this stripping and separation of the two walls.

The symptoms of prolapse will necessarily depend upon the parts involved. Commonly there is a feeling of something coming down with or without a dragging

pain. This is aggravated by standing or walking. At times in procidentia patients, their chief complaint is that of a protruding mass which is an inconvenience. Pain is most common during the early stages. The menstrual function and reproduction are usually not impaired except in cases of procidentia. Leucorrhea may or may not be present. When a cystocele is present there is usually some bladder instability and frequency of micturition. The patient often has dribbling when she laughs, coughs or sneezes. A cystitis may be present and in some cases a hydronephrosis is found due to impairment in the normal drainage of the ureter. Partial loss of control of the sphincter ani is not uncommon. One of the most common clinical symptoms is that the patient is incapacitated from leading a normal life.

Treatment of Prolapse: There are three lines of treatment to be followed: (1) rest and general massage; (2) pessaries; (3) operative treatment.

Rest and general massage is applicable to young patients in the post-partum period. With proper rest in bed and massage treatments, and helpful postures one may expect quite good results at the end of three or four weeks' treatment. This method is not of any use in long standing cases.

Long standing prolapse cases can never be cured with pessaries. The pessary is used only to relieve symptoms and to check the natural tendency of the condition to increase. The pessary is used mostly in the first and second degree cases. The watch spring pessary is the one commonly used. This can only be used when there is sufficient retentive power in the vaginal walls to retain the pessary in position. One usually selects the largest size pessary which can be worn with comfort. If the pessary is too large it will serve only to further stretch the vaginal walls and reduce their tone, thus aggravating the condition. The Napier pessary is at times resorted to in cases of procidentia when there is some good reason for not operating.

Operative Measures: The following give the most satisfactory results. (1) vaginal hysterectomy, (2) perineorrhaphy: bladder fixation and amputation of the cervix. (3) Le Fort's operation. Removal of the uterus alone in those cases is usually useless. The main part whichever procedure is carried out is to make certain that the pelvic diaphragm has been properly repaired.

Chronic inversion of the uterus is a very rare condition but needs at least mention under the heading of displacements of the uterus. In cases it is the result of an acute puerperal inversion. In a rarer number of cases it is found in association with a tumor, commonly a submucous fibroid. The puerperal cases are usually more complete than those associated with tumors.

The mucous surface is much altered, the openings of the fallopian tubes are obscured. Ulceration is common. In long

standing cases the surface presenting is covered with squamous epithelium instead of columnar epithelium. The condition is usually accompanied with irregular hemorrhage. The differential diagnosis is made from (a) a large fibroid polypus, (2) carcinoma of cervix.

The treatment of chronic inversion of the uterus is carried out usually in one of two ways (a) repositor method, (b) operative method. The Aveling repositor may be tried in the beginning. This may be given a fair trial over a period of a few weeks, the position of the repositor being altered as required.

The operative measure of choice is vaginal hysterectomy in most cases of chronic inversion. If one is anxious to retain the uterus, the old method of incising the cuff and stitching up again after correcting the incision is well worth a trial; and it often gives quite good results.

PYELITIS, URETERITIS AND CYSTITIS CYSTICA*

WILLIAM J. CARSON, M.D., F.A.C.S.

MILWAUKEE, WISCONSIN

MORGAGNI in 1761 was the first to describe cysts of the mucous membrane of the renal pelvis and

FIG. 1. Kidneys and ureters showing cysts.

ureter. He reported 2 cases, each showing a hydroureter and hydronephrosis, bilateral. Johnson, in 1816 reported a third case. Rayer, in 1837 and Rokitsky in 1861 reported cases and stated that cysts appear to be more frequent in the urinary passages than they are in or upon other excretory ducts. Virchow in 1863 compared the cysts to the mucous cysts of the vagina.

Litten in 1876 first studied these cysts microscopically and concluded that they were formed by an inflammatory blocking of the mucous glands and crypts of the mucous membrane, the retention of the secretion in these glands and crypts forming the cysts.

In 1889, Eve was convinced that they were parasitic in origin. He was supported by Morris, Bland-Sutton, Clark, Voelcker and Pisenti.

Von Brunn in 1893 described epithelial bodies (buds or sprouts) lying below the mucous membrane with an epithelial connection with the surface epithelium, and epithelial bodies showing no connection with the surface epithelium, which he designated as epithelial cell nests. These epithelial cell nests and buds are formed by the downward proliferation of the epithelium in the form of sprouts and their subsequent separation from the mucosal lining. He believed that this proliferation of epithelium was stimulated by inflammation.

Lubarsch in 1893 and Aschoff in 1894 confirmed Von Brunn's observations. Marchwald found ureteritis and cystitis cystica in a newborn, and maintained that an inflammatory process was not necessary to the formation of Von Brunn's epithelial buds or cell nests.

Stoerk, after a careful study of 13 cases of ureteritis and cystitis cystica, differed with Marchwald in that he considered the origin of the Von Brunn's cell nests to be inflammatory, and considered the cystic formation to be a secondary phenomenon.

Giani produced cystitis cystica experimentally in rabbits by the irritation of a foreign body in the bladder, and by curretting the vesical mucosa through a suprapubic cystotomy.

Morse in 1927 reviewed the literature and

* From the Department of Pathology, University of Maryland.

Read before the North Central Branch, American Urological Association, Rochester, Minn., November 22, 1929.

reported 3 cases from the Mayo Clinic with a careful microscopical study of the kidneys, ureters and bladder in 125 necropsies.

brown cysts measuring 3 mm. in diameter just above the trigon. The left ureter was dilated, measuring 10 to 15 mm. in diameter.

FIG. 2. Microphotograph of right ureter, showing cyst lined by cuboidal and columnar epithelial cells.

He found the so-called buds or cell nests of Von Brunn in 108 of the 125 cases or 86.4 per cent. In 63 of the 108 cases in which the epithelial buds or cell nests were present, inflammation was manifested by lymphatic infiltration or fibrous tissue proliferation.

Joelson in 1929 reported a case clinically diagnosed, associated with bilateral nephrolithiasis.

CASE REPORT

E. V. White, female, age fifty-eight years, Baltimore City Hospital, Autopsy No. 2604.

Clinical Diagnosis: chronic pyonephrosis and cystitis.

Urinary Tract: the bladder wall measuring 10 to 14 mm. in thickness with the mucosa being of a dark red color with 3 small yellowish

On section the wall measures 3 mm. in thickness, mucosa smooth and glistening with a number of bluish brown cysts measuring 1 to 3 mm. in diameter on its surface. There is a complete duplication of the right kidney pelvis and ureter, the ureter, draining the lower pelvis, is dilated, measuring 10 to 18 mm. in diameter. On section the wall is thickened, measuring 2 to 4 mm. with the mucosa dark red in color with a number of brown cysts on its surface, measuring 2 to 6 mm. in diameter. The upper right ureter on section shows no gross changes.

Kidneys: the capsule strips off with increased resistance, leaving a dark red granular surface. On section the cortex and medullary portion are thinned out with the architecture of the kidney poorly preserved.

The pelvis and calices are dilated and filled

with purulent urine, with the mucosa in the lower right pelvis dark red in color. Small brown cysts measuring 2 to 4 mm. in diameter are seen on the mucosa of the left kidney pelvis and lower right kidney pelvis.

MICROSCOPICAL EXAMINATION. *Kidneys:* sections show a thickening of the capsule due to adult connective tissue cells; just beneath the capsule in the cortical zone, collections of small round cells and polymorphonuclear leucocytes are seen. The capsule of Bowman shows a definite thickening due to adult fibrous connective tissue cells, some of which are stained as a pale pink homogeneous mass. The glomerular tufts in areas are stained as a pale pink homogeneous mass; in other areas they show the epithelial and endothelial cells poorly stained with the capillaries filled with leucocytes and red blood cells. The space between the capsule of Bowman and the glomerular tufts is filled with coagulated serum and fragmented cells. A number of tufts are replaced by fibrous connective tissue. In areas the glomerular tufts are seen to show their epithelial and endothelial cells well preserved. The tubules in many areas show the tubular epithelial cells poorly stained with fragmented cells and leucocytes free in the lumen. In areas, the tubular epithelial cells are distinct in cell outline with a well-stained nucleus. Between the tubules, the arterioles show moderate thickening of the tunica intima with a perivascular infiltration of small round cells, polymorphonuclear leucocytes and plasma cells. Sections from the pelvis show the surface epithelium to be swollen and finely granular in appearance. Just beneath the mucosa, a cyst is seen, lined with one or two layers of cuboidal epithelial cells well stained, with the lumen filled with coagulated sera, fragmented cells and a few polymorphonuclear leucocytes. In

the tunica propria and muscular layer, an infiltration of small round cells are seen with an occasional plasma cell.

Ureter: the muscular layer shows the circular fibers and longitudinal fibers well stained with a perivascular infiltration of lymphocytes. The tunica propria shows the elastic fibers poorly stained, with collections of small round cells between the elastic fibers. In several sections, collections of epithelial cells are seen cuboidal to columnar in type, surrounded by fibrous connective tissue cells, in areas cysts are seen lined with one or two layers of cuboidal epithelial cells with the lumen filled with coagulated sera, fragmented epithelial cells and a few polymorphonuclear leucocytes. The cysts are just beneath the surface epithelium which are well preserved. In several sections epithelial cell nests are seen communicating with the surface epithelium.

Bladder: Sections from the trigone show marked thickening of the muscular layer, due to fibrous connective tissue proliferation between the muscle fibers. The tunica propria shows marked infiltration of lymphoid cells and polymorphonuclear leucocytes. One cyst is seen which is lined by cuboidal epithelial cells, the lumen filled with fragmented cells and coagulated serum. The mucosa shows the transitional epithelial cells swollen and finely granular in appearance with necrotic material on its surface.

DISCUSSION

From the review of the literature and a study of this case, the author concludes that cystitis, ureteritis and pyelitis cystica are inflammatory in origin as described by Von Brunn in 1893. [For bibliography see author's reprints.]

INFLUENZAL FASCITIS

WITH A REPORT OF FIVE CASES*

SAMUEL KLEINBERG, M.D.

NEW YORK

SEVERAL years ago I observed a few cases in which a painful swelling appeared in the feet and heel cords following an attack of the grippe. During each succeeding winter I came across one or more similar cases and I finally became impressed with the fact that I was dealing with a definite complication of the grippe or influenza. This sequel of influenza undoubtedly occurs frequently, but has not attracted attention probably because its symptoms are usually mild, cause only moderate and temporary disability and no permanent defect. I am prompted to report my cases because I have found no reference to this lesion in any of the standard textbook articles on influenza. The following group of cases came under my observation during last spring and this year. All of them occurred during the months when the grippe was prevalent.

CASE REPORTS

CASE I. Anna W. (Hospital No. A23-076), twenty-eight years old, was admitted to the service of Dr. Royal Whitman on May 6, 1927. Her chief complaint was pain in her feet. Three weeks previously she was ill with the grippe. She had a moderate rise of temperature and was confined to bed for two days. She was gradually recovering from the general depressing effects of the grippe when her feet became painful. Three days before her admission to the hospital the pain was very severe, and on the following day a swelling appeared in each foot making walking uncomfortable and difficult.

Upon her admission to the hospital she was unable to walk. She had a marked pallor, such as is common following the grippe. In the right foot there were two swollen areas, one on the inner and the other on the outer side of the ankle. The inner swelling was about 5 by 3 in. in area. It involved the astragalonavicular region and extended upward to above the malleolus. The swelling was not well defined

but faded gradually into normal tissue. The skin in the affected part was bright red, hot, glossy and very sensitive to pressure. Upon palpation it was evident that the subcutaneous tissues were swollen. There was a similar but less marked lesion on the outer side below the malleolus. The swelling did not extend to the sole of the foot but the plantar tissues were sensitive to pressure.

In the left foot there was a red, swollen, painful area on the inner side of the ankle, chiefly in the region of the attachment of the tibialis anticus tendon, and also a small painful swelling on the outer side of the ankle along the peroneus brevis.

The patient was kept in bed and given large doses of tolysin for her pain. Large quantities of fluids were given by mouth to counteract the general depletion. The temperature fluctuated between 100 and 102.8°F. Within five days her fever subsided and the local symptoms disappeared. On the eleventh day she was discharged cured. Two blood cultures were negative, the blood chemistry was normal, the urine showed no abnormal findings and the blood count was negative except for a moderate anemia.

This patient had, I believe, an acute inflammation of the subcutaneous fascial tissues, a fascitis, on the lateral surfaces of both feet and in the plantar region of the right foot, secondary to an influenza and probably due to the same bacterium.

CASE II. Edward G. twenty-eight years old was treated at the Hospital for Ruptured and Crippled (Case No. B1-919) on the service of Dr. Royal Whitman. He was admitted on April 19, 1927 complaining of pain in the back of the left knee, the soles of both feet and the right hand. These symptoms came on after an illness that probably was the grippe, but may have been a tonsillitis.

Examination upon admission to the hospital showed that the patient was in good general condition. There was a painful swelling in the plantar region of each foot. The skin was not red

*Read before the Section on Orthopedic Surgery, New York Academy of Medicine, April 19, 1929.

from the inner border to well above the malleolus. It occupied the entire inner aspect of the ankle. The swelling was diffuse and faded gradually into surrounding normal tissue. On the outer aspect of the ankle the swelling was similar, but less extensive. The skin was bright red and glossy. There was also a moderate swelling about the lower part of the heel cord. The skin here was not red. The ankle motions were restricted by the pain in the swollen areas, but the ankle joint itself was not involved. The swollen areas were very sensitive even to light pressure. The tissues over the left sternomastoid muscle, the right great trochanter and the lumbosacral joint were tender to touch. There was no discernible swelling or redness of the skin in these latter areas. Tolysin, aspirin and even morphine gave little relief.

On the following day a red, hot, very painful swelling was found on the inner side of the left foot similar in appearance and distribution to that on the right foot. The tissues about the left heel cord were also swollen, sensitive to pressure and painful during motions of the foot, especially dorsiflexion. A painful spot appeared on the outer side of the left thigh slightly below and behind the great trochanter. Application of heat externally with a baking lamp increased the pain. As the symptoms were becoming worse and the pain was intense, it was determined to remove her to a hospital for observation, and she was admitted to my service at the Hospital for Joint Diseases. X-ray pictures of both feet and a blood count were negative. It occurred to me to apply wet dressings of a boric acid solution to the swollen parts. These were changed every hour, day and night and were kept continually covered with oiled silk. This procedure worked like a charm. The pain immediately subsided. The swelling, redness and sensitiveness rapidly diminished. A slight fever persisted for about a week. On the third day after admission to the hospital the tissues about the sternomastoid and the attachment of the left adductor muscles to the pelvis became painful and sensitive to touch. There was no redness or swelling in these areas. These symptoms lasted only several days. The urine was negative except for a trace of albumin. A blood culture was negative after seventy-two hours of incubation.

The patient was discharged on the eighth day after her admission, because she had to attend the funeral of her mother. When she

left the hospital there were no symptoms in either lower limb, but her temperature was 99.5°F., indicating that she was not entirely well. Two days later she returned on account of a slight relapse of the swelling, redness and pain in her feet. The application of wet boric acid dressings gave immediate relief. In five days her temperature was normal and all symptoms disappeared. She left the hospital and has remained well since.

CASE V. Mr. B. came to my office complaining of a painful swelling on the front of his left leg. This extended upward from the ankle for about 4 in. The symptoms which came on about a week after a mild cold or grippe during the recent epidemic of influenza in New York, had existed for about five days when he consulted me, and they were getting worse.

Upon examination I found a diffuse swelling on the front of the lower part of the leg. There was no redness, but there was slight local heat and marked sensitiveness to pressure. An x-ray picture was negative. He was immediately urged to rest in bed and apply boric acid dressings. He did so and obtained complete relief and a cure in about six days.

The cases described have many common characteristics. All of them were adults and were ill when the grippe was prevalent in the city. In all the patients, including those observed prior to 1927 and not reported because I had not kept a record of them, the symptoms came on from four to seven days after an attack of the grippe. The grippe had not been of a severe nature in any of the patients.

The local lesion occurs most often in the feet, but may occur in the subcutaneous fascial tissues of any part of the body. The characteristic clinical appearance is a painful swelling in the sole of the foot and around the heel cord, that is, in the plantar fascia and the areolar tissues about the tendo Achillis. Elsewhere it occurs in the neighborhood of tendons and subtendinous bursae. When the lesion is in the lower limb walking is difficult or impossible, and the pain is increased by any movement of the limb. Pressure upon the swollen area causes pain. The skin is usually white and shiny. When the inflammation involves the skin, it is red, hot,

glossy and very sensitive to pressure. The essential pathologic change is, I believe, an inflammation of the subcutaneous fascial tissues. Since the lesion has been found only in patients who have or are just getting over an attack of the grippe or influenza, it appears to me logical to at least assume that it is due to an invasion of the fascial structure by the bacterium of influenza or its toxins. I have had no opportunity to obtain bacteriological proof of this conclusion which I, consequently, base on clinical evidence only. As the inflammation of the subcutaneous tissues is a complication of influenza, I believe that the term *influenzal fascitis* is appropriate since it describes the pathology of the lesion and its likely etiology.

The treatment, from my experience in the last two cases, is fortunately simple. It consists of rest in bed and the application of wet dressings to the inflamed parts. The inflammation subsides in a few days and leaves no residual defects. From the relapse of the painful swelling in some of the cases it is advisable to continue rest in bed for at least a week after freedom from all symptoms.

DISCUSSION

DR. A. DEF. SMITH: I would like to know why Dr. Kleinberg is so certain that this inflammation is confined to the fascia and subcutaneous tissues. There are other tissues in the same regions, tendon sheaths, muscles, joints and periosteum, and I don't see why they may not be involved as well as the fascia. There is not any pathological proof, of course, that it is the fascia.

DR. RALPH C. KAHLE: I have had the good fortune of seeing several of these cases of Dr. Kleinberg's and have had the opportunity of observing a case of my own, a man thirty-six years old, with a typical history of four days after the initial grippe developing symptoms with swelling of the inner side of the ankle which subsided after rest and applications of warm boric acid solution.

This afternoon at the Cornell Clinic I saw another case with a similar history, six days after the grippe, with a swelling on the inner side of the ankle. It was just as Dr. Kleinberg described, hard, tender, reddened, etc. There was nothing present to make any one think the lymphatics were involved nor were the signs of venous thrombosis. For want of another term, I called it the same as Dr. Kleinberg and used the same treatment as in the other case.

DR. CHARLTON WALLACE: How can one tell the difference between fascitis and cellulitis?

DR. SIGMUND EPSTEIN: The history of grippe is very often erroneous. A case of painful foot and calf was seen yesterday; three doctors said that he had grippe: a severe phlebitis of the calf branches was the real diagnosis. His troubles had lasted five weeks. I find similar swellings of the foot, ankle and tendo Achilles are very common. Some of them are red. They consist of subcutaneous indurations and are infectious in origin. The British call them *fibrositis*; the dermatologists call them *erythema nodosum*.

DR. KLEINBERG, closing: I am sure that the muscles in cases of *influenzal fascitis* are not involved. In most of the cases the swelling is limited to the sole of the foot and there is no pain on contraction of any of the muscles of the foot or leg except when the motion causes tension on the swollen area. In several cases the swelling extended over the external malleolus and it is often in the region of the heel cord where there are no muscles. When one considers the composite picture of *influenzal fascitis*, one readily concludes that there is no involvement of the muscles. The inflammation is usually limited to the subcutaneous tissues; occasionally there is involvement of the skin. So far as cellulitis is concerned there is no difficulty in differentiating fascitis from the ordinary type of cellulitis. In the latter condition, there is an enlargement of the glands, a lymphangitis and a severe toxemia. These are absent in fascitis. Periostitis can be excluded, first, by the fact that the x-ray pictures are negative and secondly, by the fact that pain upon pressure is present even to light touch when manifestly there is no irritation of the periosteum. I have not seen any untoward sequelae following *influenzal fascitis*.

GLUCOSE IN THE TREATMENT OF TOXEMIAS OF PREGNANCY*

W. T. McCONNELL, M.D.

LOUISVILLE, KY.

A LIST of the various theories of the etiology of the toxemias of pregnancy would consume more space than is allotted for this entire paper. An enumeration of the many procedures employed in the treatment of these conditions would be equally voluminous. We will, therefore, limit our discussion to a consideration of carbohydrate metabolism in these toxic conditions, and some observations on the phenomena encountered in the administration of glucose (or dextrose) in the treatment thereof.

The most common forms of toxemia of pregnancy are the vomiting of the early months of gestation, culminating in hyperemesis gravidarum, and the disturbances of the latter months, terminating in eclampsia.

The contributing factors in the etiology of the early toxemias are many.

The immediate cause of such disturbance is the presence in the blood stream of substances acting as toxic agents exerting a deleterious influence upon metabolism, with the resultant digestive disorders.

In the average case, the reserve forces are sufficient to adjust these difficulties in a few weeks, so that the patient will continue her pregnancy with a good degree of comfort and well-being.

In some few cases the distributing element is of such a severe nature that the maternal organism is not able to successfully combat these evil forces, the nausea and vomiting become more and more severe, until nothing is retained in the stomach.

This extreme condition, fortunately, is not so common as formerly, due largely to better supervision of the patient and more energetic efforts to correct the condi-

tion producing the ordinary vomiting of pregnancy. Few cases indeed need progress to the state of hyperemesis gravidarum, if proper attention is paid to the earlier and milder forms of vomiting.

It has been shown by Paul Titus¹ and others that in practically all of these cases, whether mild or severe, a marked carbohydrate disturbance is present. As soon as pregnancy is established, the carbohydrate needs of the mother are markedly increased. When the endocrines governing metabolism are able to care for this sudden need, there is no marked disturbance; when, however, the requirements develop more rapidly than the metabolic hormones are able to adjust themselves to the new conditions, digestive disturbances follow.

The developing placenta requires a great amount of glycogen,² and the liver is called upon for an increased supply. In multiple pregnancy the placental area and volume being greater, a still larger demand is made upon the store of glycogen and a greater tax is put upon the endocrines. If the metabolic forces are not able to supply the liver with sufficient sugar to insure an adequate glycogen reserve, hepatic degeneration results, and glycogen production falls, even below its ordinary level. Thus a vicious circle is thereby established. The more the liver is damaged, the less glycogen is produced, and the more the glycogen reserve is depleted, the more liver damage ensues.³

It is probably this sudden need that first throws the endocrines out of balance, and once disorganized, they in turn fall below ordinary efficiency.⁴

Before this phenomenon was so well understood, the usual method of treatment of hyperemesis gravidarum was an early

*Read before The American Association of Obstetricians, Gynecologists and Abdominal Surgeons, Memphis, Tenn., September, 1929.

emptying of the uterus. This method of necessity sacrificed the fetus and frequently the mother, since by the time the disturbance progressed to the stage of actual hyperemesis, the maternal condition was such that the shock of abortion was sufficient to produce a fatal issue for the mother. The problem in the treatment of this condition, therefore, was to supply glucose to the maternal organism in such a form and in sufficient quantities, that the liver would have a chance to recuperate, the endocrines have opportunity to adjust their functions to the new requirements, the maternal organism would be adequately nourished, the dehydration combated, and the fetal needs met.

The fact that the employment of such a system of treatment for hyperemesis is successful, both regarding mother and child, making therapeutic abortion seldom necessary, seems to prove its efficiency.

While various modifications in the technique are recommended by different operators, yet the glucose treatment of hyperemesis has been developed to a point where the essential features form a common basis for these methods.⁵

The following case is typical of the condition under consideration and the treatment employed, and is here reported as an illustration of the usual results obtained by us in hyperemesis:

CASE I. Mrs. M. S. B., para II, aged thirty-seven, was referred to me on June 9, 1928. Examination showed patient to be dehydrated, dry, parched skin, heart rate 130, temperature 100, blood pressure 120-85, urine negative, for sugar, albumin, casts or pus. She gave a history of having her last menstrual period 3 months previously (March 5), of being able to retain practically nothing by stomach for the past week. Complained of severe epigastric pain, sleeplessness, diplopia, pronounced weakness and prostration.

Vaginal examination revealed a much larger uterus than would be found in a 3 months' pregnancy.

Treatment. One ampule of corpus leutea was immediately given intravenously, without any beneficial results.

She was removed to the Kentucky Baptist Hospital. Everything by mouth was discontinued, 1000 c.c. of 5 per cent glucose in 1 per cent. saline were given intravenously, the administration being completed in forty-five minutes. This was repeated daily for five days, when the urinary output reached the amount of in-take; 4 oz. of 10 per cent glucose containing 60 grains of potassium bromide were instilled into the rectum every four hours.

The nausea and vomiting stopped immediately after the first injection of glucose: the abdominal pain ceased with fifteen minutes; neither of these symptoms recurred.

On the third day some vaginal bleeding and cramps occurred, but subsided two days later. The diplopia disappeared about the seventh day. The pulse and temperature returned to normal on the third day.

From the third day fluids were given by mouth, at which time the rectal instillations were discontinued, and elixir bromidum and elixir luminal, each drams 1, were given by mouth three times daily. After the fifth injection of glucose the temperature went up to 102 and the pulse to 120, remaining thus for several hours, then returning to normal. Soft diet was given after the fifth day, and regular diet on the seventh.

The patient left the hospital on the tenth day in good condition, with no recurrence of symptoms.

As pregnancy progressed, hydramnios developed so markedly that no diagnosis of position or presentation was possible by auscultation or palpation. On September 5, twin pregnancy was diagnosed by x-ray, showing about seven months' pregnancy. She was readmitted to the hospital on October 10, because of discomfort due to abdominal enlargement.

By November 1, the hydramnios had become so marked that the respiratory and circulatory embarrassment demanded interruption of pregnancy.

The babies were both female, weighed 4 lbs. 6 oz., and 5 lbs. 6 oz., respectively, apparently single-ovum twins, well-developed and healthy. Mother and babies left the hospital in good condition, and today, more than six months later, are all thriving and well.

Another interesting case was one of hyperemesis in an unmarried primipara, who was also suffering from an acute nephritis due probably to the taking of

large amounts of turpentine with abortive intent.

CASE II. This patient, R. C., para 1, fourteen years old, four months' pregnant, was brought into the Louisville City Hospital in a semi-comatose condition. Her history showed she had taken 1 oz. of turpentine several times in the three weeks preceding admission.

She was given ten administrations of glucose without relief of the emesis.

A therapeutic abortion was done twenty-two days after admission, after which vomiting ceased, and patient recovered.

The blood chemistry taken at intervals during this period showed: non-protein nitrogen, 75, 93.6, 194.8, 113, 85.5, 88.2; urea, 38, 70, 88.2, 70, 40, 46; creatinine, 8, 7.5, 10, 9, 6, 4.8; plasma bicarb., 73, 150, 140, 130. An initial blood-sugar reading showed 153.

It will be seen that the blood chemistry in this case showed improvement under glucose, even though the vomiting was not controlled thereby. We have seen other such cases showing severe vomiting, accompanied by acute nephritis, in which glucose did not relieve the vomiting. In all cases of hyperemesis, however, unaccompanied by an acute nephritic groundwork, glucose has been eminently successful.

The 2 cases above reported illustrate the results obtained by glucose in hyperemesis, first, when the hyperemesis has for its primary basis a carbohydrate deficiency due to metabolic upset, and, as in the latter instance, where the vomiting is incidental and the basic condition is an acute damage to the other organs, especially the kidneys.

Regarding the rôle that carbohydrate deficiency plays in the late toxemias of pregnancy, much valuable work has been done recently, and there is a strong probability that out of this will soon be developed more definite knowledge of the relationship of carbohydrate metabolism to eclamptic conditions.

Paul Titus⁶ has brought out some very pertinent points in this connection, one of the most striking of these being his

findings in blood-sugar levels during the acute eclamptic state. He has shown that the convulsions are immediately preceded by a sudden marked drop in blood-sugar; that the hypoglycemia in eclampsia is relative and not absolute: that is, that the average blood-sugar level in this condition is not necessarily lowered, but drops markedly only in relation to a convulsion. He further suggests:

The chief difference between the clinical symptoms of the toxicoses of early and late pregnancy is due to the fact that the former is a slow, and the latter an acute, rapidly progressing process. In early pregnancy the fetal requirements are less and the demands are more gradual, so that the glycogen depletion of hyperemesis rarely is swift enough to cause convulsions. Occasionally, however, we see that fulminating process termed acute yellow atrophy of the liver which is pathologically identical with hyperemesis but is so acute that eclampsia-like convulsions usually occur.⁷

In our own experience there would seem to be some evidence of such a relationship as Titus describes. The chief clinical differences in the early and late toxicoses, as we have observed them, are the marked elevation of blood-pressure, albuminuria, and convulsions, present in eclampsia, while absent or negligible in hyperemesis. In eclampsia we have also failed to get from the administration of glucose the phenomenal benefits obtained in the treatment of hyperemesis. As to liver pathology, we have not found in all fatal cases of eclampsia the typical acute yellow atrophy lesions of this fulminating toxemia of early pregnancy.⁸ In view of the above variations, the question arises if the differences encountered in early and late toxemias would not have to be accounted for by a more basic factor than the mere element of rapidity of development. For example, would the rate of the process account for the elevation of blood-pressure in eclampsia, while normal in hyperemesis? It would seem to the writer that the severe manifestations of hyperemesis are more nearly the result of glycogen depletion,

TABLE I

| Name | Para. | Age | Diagnosis | Glucose given | | Blood-pressure before glucose administration | Blood-pressure 1 hour later | Blood-sugar before glucose administration | Blood-sugar 1 hour later |
|-------|-------|-----|-----------|-------------------|----------------|--|-------------------------------|---|--------------------------|
| | | | | c.c. | Per cent | | | | |
| L. P. | v | 29 | Eclampsia | 500 500 | 10 10 | 205/120 185/120 | 200/110 185/110 | | |
| J. D. | vi | 35 | Eclampsia | 450 | 10 | 185/120 | 175/100 | 97.5 | 166. |
| E. P. | i | | Eclampsia | 500 | 20 | 148/98 | 142/90 | | |
| H. M. | vi | 38 | Eclampsia | 500 500 | 20 20 | 138/90 170/90 | 140/80 150/80 | | |
| M. P. | iii | 27 | Eclampsia | 500 500 400 | 20 20 20 | 230/110 150/100 199/106 | 210/106 140/100 196/103 | 111 | 200. |
| E. G. | i | 17 | Eclampsia | 500 | 12 | 170/110 | 130/80 | | |
| K. W. | i | 21 | Eclampsia | 500 | 20 | 152/105 | 150/105 | 111 | 112 |
| A. J. | x | 31 | Eclampsia | 250 200 500 | 20 20 20 | 180/140 184/124 190/125 | 140/105 174/120 170/115 | 80 | 88.3 |

The average show a drop in blood-pressure of 12 points in the systolic and 9 points in the diastolic pressure. Blood-sugar shows a rise of 40.5 points.

while the carbohydrate disturbances of eclampsia are more directly the result of the toxemia, and occur as a part of the general metabolic upset; or in other words, an incidental occurrence in eclampsia rather than the primary manifestation as in the early toxemia.

We have recently been interested in the influence of intravenous glucose upon blood pressure and blood-sugar in eclampsia. In the accompanying table, it will be seen that both the systolic and diastolic pressure were lowered in practically every instance and no elevation in any case.

The average for all cases showed a lowering of 12 mm. for the systolic and 9 mm. for the diastolic. The blood-sugar, however, was elevated in each instance, the average being 40.5 points. In each of these cases, blood-pressure readings were taken at frequent intervals after the discontinuance of the glucose administration. Before the glucose was given the reading was 180/140; 15 minutes after the completion of administration it was 140/100; after 25 minutes, 160/100; after 35 minutes 155/110; after 45 minutes 150/100; one hour after discontinuance

the reading was 140/105. This patient passed 1000 c.c. of urine within one and one-half hours after glucose administration. We have noticed in practically all eclamptic cases that the urine is more copious after glucose administration. This may account in part for the fact that the blood-pressure is lowered by the glucose, even though the blood volume is temporarily increased. Yet we believe it would not wholly account for this phenomenon. The blood-pressure is lowered before the kidneys would have time to react to this extent. There must be a neutralizing of the vaso-constrictor effect of the toxin, whatever that toxin may be.

The writer would hesitate to add even one more theory to the already long list of speculations regarding toxic action in eclampsia, but in an earnest effort to account for the various phenomena observed in the treatment of this condition, one naturally seeks to find some plausible explanation, and a number of observations already accepted as authentic would, to our mind, offer a possible reason for certain clinical results in the employment of glucose.

In the first place, blood-sugar falls rather suddenly immediately preceding a convulsion. Then the eclamptic convulsion is very similar to the manifestations seen in shock from an over-dose of insulin.⁹ Also, blood-pressure is lowered by glucose administration, even though blood-volume is temporarily increased. The use of glucose, too, seems to have a marked influence in lessening the number of convulsions. Therefore, it would seem reasonable to conclude that the toxin of eclampsia stimulates the production of insulin, and that the convulsions are precipitated, in part at least, by the sudden appearance in the blood stream of an overload of insulin. If this be true, the beneficial influence of glucose could be accounted for in part by its neutralizing effect upon this insulin.

As to the amount of glucose used, it will be seen by the accompanying table, 500 c.c. of a 20 per cent solution were usually employed. In instances where we have used 1000 c.c. of a 10 per cent solution, results were not markedly different.

As to the amount of glucose which may be tolerated by toxic patients some very interesting work has been recently done by Dr. G. A. Hendon.¹⁰ He uses a continuous flow of glucose solution which he styles "venoclysis." It has been the writer's privilege to observe a number of cases treated by this method, and the results obtained have been spectacular. This procedure is as yet in a more or less experimental stage, but enough work has already been done to demonstrate some very interesting facts regarding the intravenous administration of glucose.

To Dr. Rudolph Matas probably belongs the credit of first calling attention to this method. In June, 1923, he reads a paper before the American Surgical Section on "Continuous Intravenous Drip."¹¹ The method proposed by Matas did not come into popular use, however, probably due to the following difficulties: (1), inability to keep the solution at an even

temperature; (2), inconvenience to the patient, the arm having to be held immobile during the administration; (3), the clogging of the needle or canula by the solutions.

These difficulties have apparently been obviated by the technic and apparatus employed by Hendon. He has used this form of administration in something over 100 cases. A 5 to 10 per cent solution of anhydrous glucose in freshly distilled water is the concentration usually employed. The average amount given an adult is 4000 c.c., or one gallon, every twenty-four hours. The average duration of the continuous administration in all his cases is about seven days, one patient, a gastric ulcer case, receiving 5000 c.c. of a 5 per cent daily for sixteen days.

In none of these patients has there been any untoward results; there have been no symptoms of hyperinsulinism (a probable complication suggested by Thalheimer),¹² except in two hyperemesis cases where insulin was given with the glucose. The two patients showed evidence of slight insulin poisoning, which disappeared immediately upon discontinuing the insulin, the glucose being continued.

The concentration of the solution employed has been determined by the point at which sugar appears in the urine. If glycosuria appeared, the concentration is reduced. Practically all of them tolerate a 5 per cent strength, and many of them 10 per cent without glycosuria. In those cases where blood-sugar determination has been done, the average level has been about 150, the highest reading being 169. In this case, however, no sugar showed in the urine.

One reason why such apparently large quantities can be taken is that no sudden load is put upon the powers of assimilation, or upon the circulatory function. The usual rate of continuous administration is one drop per heart beat.

Woodyatt, Sansum and Wilder¹³ claim that a normal individual can assimilate without glycosuria 0.9 gm. of glucose

per k. of body weight per hour. In other words, a man weighing 150 lbs. would take care of 2.5 lbs. per day.

In Hendon's series the patients received from 1 to 2 lbs. per day.

The cases in which this method has been employed include those of severe toxemia, septicemia and conditions in which oral feeding has, for any reason, been impracticable. These patients require no water or food by mouth during the administration.

A number of these cases have been those of desperate hyperemesis gravidarum, in which the use of glucose by the usual methods was unsuccessful, while with the continuous drip the condition was completely relieved.

The essential features of the apparatus used are two thermos bottles of 1000 c.c. capacity each, suspended in a wire frame and attached to a Y-tube, which is in turn connected to a Murphy drip tube; from this a single rubber tube leads to a gold-plated silver canula. This canula is inserted through a phlebotomy opening into a vein just above the bend in the elbow. The vein is ligated distal to the insertion, and a ligature of umbilical tape is passed around the canula in the vein, held in situ by a shoulder on the canula. The wound is closed and a sterile dressing applied. The rubber tubing is fixed to the arm by strips of adhesive, permitting the patient to move the arm at will during the administration. The use of two thermos bottles permits the employment of one while the other is being filled. The thermos feature keeps the solution at a constant temperature.

It is noteworthy that in no case so treated has there been any reaction or other ill effects of the glucose administration, and further that the desired results have been obtained in every instance.

If the further results of this method prove as desirable as those already obtained, it will broaden the field of usefulness of glucose therapy, especially in the treatment of those severe toxemias of early pregnancy where other less intensive methods fail.

SUMMARY

From our observations enumerated herein, the following points might be summarized:

1. In the early toxemias of pregnancy, where the disturbance is of metabolic origin, the employment of glucose is probably our best single therapeutic agent.

2. In those early toxemias of renal origin, glucose is of value as a supportive and detoxicant, but does not relieve the hyperemesis as completely as in the toxemias of primary carbohydrate deficiency.

3. In the late toxemias, glucose is effective in lowering blood-pressure, neutralizing the toxin and lessening the number of eclamptic convulsions.

4. Recent experiments with the continuous drip method of the intravenous use of glucose tend to show that larger quantities of this agent can be used, and with more beneficial results, than was formerly supposed.

INTRAPERITONEAL INFUSION & AUTOTRANSFUSION

IN ABDOMINAL SURGERY*

G. W. COTTIS, M.D., F.A.C.S.

JAMESTOWN, N. Y.

THE importance of an adequate supply of fluids after operation is generally recognized even by surgeons who still dehydrate their patients by preoperative catharsis and restriction of water intake. The use of the Murphy drip, hypodermoclysis and intravenous infusions is almost universal. In all, or nearly all clean abdominal operations these procedures are unnecessary annoyances to the patient, the surgeon and the nurses.

As shown by Wegner, absorption from the peritoneal cavity is so rapid that the injection of potassium cyanide causes death almost instantly, just as if it were injected into the blood stream. Normal salt solution is absorbed directly into the blood stream. Dandy and Rowntree¹ proved this by injecting a solution containing phenolsulphonephthalein as an indicator. The dye appeared in the urine in six minutes and in the lymph only after thirty-seven minutes. In an hour, 56.4 per cent of the dye was regained from the urine, while less than 0.1 per cent appeared in the thoracic duct. Clinical confirmation of this work is described below.

Why not utilize the peritoneum to furnish the patient with a continuous supply of water during the time when he needs it most? There is no limitation to the amount that can be absorbed except the capacity of the abdominal cavity. The technic is simple. After the last peritoneal suture has been inserted and before it has been tied, a catheter or small enterostomy tube is inserted and normal saline solution at 100° or 104°F. is poured by means of a funnel until the solution begins to run out around the tube. In the average case about 1 liter is used but after the removal of a large tumor, much larger amounts are taken.

The benefit of this procedure is twofold. It immediately overcomes the chilling of the peritoneum which is unavoidable in any extensive operation and it assures a constant intake of water for the six or eight hours during which it is needed most. Whether it prevents adhesions is debatable. The striking absence of postoperative thirst would justify the use of the method regardless of the general benefit to the patient. Since adopting this method, we have discontinued the use of the Murphy drip except where the intraperitoneal infusion is contraindicated by the presence of pus or by drainage of the wound.

The power of the peritoneum to absorb fluids as shown by animal experiment has already been mentioned. Clinically, we have checked it by the following experiment:

To 1 liter of normal saline solution, we have added 1 c.c. of standard solution of phenolsulphonephthalein solution. The urine has been collected by catheter at intervals of one, two and six hours and quantitatively tested. The average percentages of excretion are:

| Hours | Per Cent |
|-------|----------|
| 1 | 14 |
| 2 | 37 |
| 6 | 59 |

Since these figures are dependent not only on the rate of absorption but on the rate of renal excretion, it is obvious that a considerable degree of absorption begins immediately and the greater part of the solution has entered the circulation during the first six hours.

INTRAPERITONEAL AUTOTRANSFUSION

Many reports have appeared in recent years of the intravenous infusion of citrated blood taken from the abdomen,

* Submitted for publication January 18, 1930.

especially in cases of ectopic pregnancy. This is a logical procedure, especially when the abdomen is full of fresh unclotted blood from recent hemorrhage, whether from ectopic pregnancy or ruptured liver or spleen. It is much simpler and apparently as effective to citrate the blood and return it to the peritoneal cavity with the routine saline at the conclusion of the operation. We have done this particularly when hysterectomy was performed for bleeding fibroids. These patients are frequently anemic and it is desirable to save them from further loss of blood. Especially when dense adhesions must be separated, a good deal of bleeding is often unavoidable. Lesage² found in experimental animals that untreated blood is absorbed rapidly after three hours. Bizzozero and Golgi,³ using defibrinated blood, found an increase in the number of red cells twenty minutes after injection. The maximum increase came after about two days. Hertzler⁴ says, "The absorption of non-coagulated blood seems to be similar to the absorption of isotonic solutions in general."

By means of the ordinary Pool suction tube, free blood is aspirated into a sterile bottle containing citrate solution. A basin containing citrated saline solution is also placed conveniently so that an assistant can rinse in it each sponge as it becomes soaked with blood. At the conclusion of the operation, the citrated blood in the bottle and the saline-blood mixture in the basin are strained through gauze and warm saline is added to bring the volume up to 1000 c.c. and the temperature up to 100°F. The mixture is then introduced as in the routine saline infusion previously described. We have been doing this for

nearly three years and have never seen the slightest ill effect. Many pediatricists have used the intraperitoneal route in administering citrated blood to infants, apparently with complete satisfaction. This seems to answer the theoretical objection that blood is a foreign body in the peritoneal cavity.

When intravenous autotransfusion is used every precaution is taken to prevent breaking up the red cells. This is emphasized by Farrar,⁵ who says: "Care was taken not to stir or shake the blood to avoid injury to the red cells." Clots must be eliminated. An extra assistant is necessary.

In the intraperitoneal method, a few clots do no harm. Ruptured red cells are absorbed and the hemoglobin utilized. The blood-soaked sponges may be squeezed and even rinsed out in the citrate solution, so that the greatest possible salvage is effected. No extra assistant is required. If no suction is available, the greater part of the blood can still be saved by sponging or ladling it from the abdomen.

In the event of severe hemorrhage into the abdominal cavity, whether it occurs before or during operation, it is not good surgery to throw away the blood. This method of returning it to the patient is simple, safe and effective. It is a conservative measure which is worthy of more general use.

THE PORGES-POLLATSCHEK SKIN TEST FOR PREGNANCY*

HYMAN STRAUSS, M.D.

BROOKLYN, N. Y.

A SIMPLE and yet reliable skin test would be highly desirable and of vast importance in the diagnosis of early pregnancy. The importance of such a test is particularly obvious in post partum cases where a slight increase in the size of the uterus occurring together with a lactation amenorrhea must be ruled out as signs of pregnancy. Its value is equally apparent in the diagnosis of a gestation at the premenopausal age. In cases of young girls of irregular menses and also of recognized social status, a skin test for pregnancy would be invaluable since it would eliminate a highly embarrassing and perhaps a presumptuous pelvic examination. Even in legal cases wherein the history must be disregarded and pregnancy diagnosed early, such a test would be of vast assistance and, last but not least, in instances where the physician is called in to differentiate between an ectopic and some non-surgical condition.

The Ascheim-Zondeck test for pregnancy might well be relied upon in all such conditions except in an ectopic gestation; it is very reliable since it gives 95 per cent to 98 per cent correct results in the hands of an experienced man. However, one must have facilities for keeping mice. This is a very difficult task for the following reasons: they must be virgins of a certain weight and age, and at that age, sex is hard to determine; occasionally they kill each other; frequently they die before injection; many die from meningitis or from toxic urine. Moreover the urine of a patient receiving antiluetic treatment kills the mice within forty-eight hours. And finally, it takes almost a week to make a diagnosis, thus rendering this task practically useless in ectopic gestation.

In the Vienna letter to the *Journal of the American Medical Association* on Aug-

ust 17, 1929, a simple and yet reliable skin test eliminating these objections was briefly mentioned. Dr. Otto Pollatschek and Dr. R. Porges of Vienna were injecting 0.2 c.c. of the hormone of the anterior lobe of the hypophysis intracutaneously. "If the woman is not pregnant, a distinct red circle, about an inch in diameter, is formed after a few hours at the sight of the injection, and remains visible for twenty-four to thirty-six hours. In pregnant women, there is no reaction." This was explained as a specific skin reaction which was an entirely new observation for hormones, and as analogous to the Schick, Dick and Pirquet test for infectious toxins.

Not convinced by the explanation of the mechanism involved, but interested in checking up the results of the European investigators, I obtained permission from the heads of the various departments of the Kings County Hospital to conduct this experiment. The only preparation of anterior pituitary hormone available in the United States was antuitrin. Later I was able to procure prolan, the preparation that the Viennese physicians used.

In order to avoid drawing unwarranted conclusions, I chose a series of over 500 consecutive cases. Of this original number, 50 were excluded because of failure to return for a reading. I discarded an additional 100 in order to thoroughly familiarize myself with the procedure and to eliminate trauma as a possible factor. Thirty more cases were thrown out due to the intense pigmentation of the skin. However, the greatest factor against this test was the indefiniteness of the results, which made us disregard 150 cases. The skin reactions were of such a nature, in this latter group, that 2 or 3 observers could not agree on the readings. Of the total number of 524 cases, only 184 remained, which are tabulated as follows:

* Submitted for publication, January 21, 1930.

TABLE I

| Condition | Total Number (Antuitrin) | Results |
|--------------------------|--------------------------|----------|
| Males..... | 6 | 5+, 1- |
| Menopause..... | 1 | 1- |
| Postpartum..... | 8 | 5+, 3+ |

The results obtained by the writer as just indicated lead to only one obvious conclusion: namely, that the so-called

Porges-Pollatschek skin test for pregnancy is neither definite nor reliable. Subsequently, the writer's findings were confirmed by the very authors of this so-called test, for towards the latter part of the investigation, a communication was received from Dr. Porges himself, wherein he admitted that as his series of tests increased his percentage of error ran as high as 18 per cent. Obviously, this was quite a radical departure from the earlier assertions regarding the absolute reliability of this test, for originally it was claimed that the test had been proved correct in all but one instance, that of a woman who had a hypophyseal tumor.¹

In conclusion, the writer would like to express his gratitude for the kind assistance and cooperation rendered him by Drs. Philip Smith and Raphael Kurzrock of Manhattan and Dr. M. Walzer of Brooklyn, but for whose helpful suggestions many of the obstacles which confronted him could hardly have been overcome.

¹ Further confirmation of the writer's findings has since appeared in the *Zentralbl. f. Gynak.*, 53 Jahrg. 16, Nov. 1929, No. 46, p. 1920, wherein Dr. Alfred Deutsch of Vienna, after a series of similar experiments, announced conclusions coinciding with those of the writer.

THE SURGICAL TREATMENT OF UTERINE FIBROMYOMA*

E. H. CHAPIN, M.D.

COLUMBUS, OHIO

UTERINE fibromyoma is the most common nonmalignant new growth occurring in the human body and relatively speaking, constitutes the most frequent pathological condition the gynecologist is called upon to treat. In a personal series of 416 pelvic operations taken chronologically, the writer found the presence of the ordinary lobular levicellular fibromyoma of the uterus in 68 cases or 16.3 per cent. All the patients were white women with the exception of one. These findings are considerably higher than those of Hofmeier and Essen Moler who estimate that they constitute from 4.3 to 4.7 per cent of all gynecological conditions. However, they are within fair keeping with those of Lynch's¹ and Frank's² most thorough accumulative data which shows, varying with different investigators, that 20 to 30 per cent white and 30 to 60 per cent colored women are prone to the development of uterine myomas, the fastigium being reached between thirty and fifty years of age.

There is no questioning the fact that thousands of symptomless uterine fibromata go unrecognized and that many are discovered accidentally. While a few unauthenticated cases have been reported as occurring before puberty, it must be recognized purely and simply as a disease of the child-bearing period of a woman's life, receiving its stimulus for development as a result of congestion incident to menstruation, confirmed in the fact that with the establishment of the menopause, the tumors tend to atrophy and degeneration.

ETIOLOGY

Many theories have been offered as to the probable origin of fibromyomas, the

most feasible of which is that expounded by Roesger, Gottschalk and others that they develop from the musculature of small arteries.³ However, not any border on a hypothesis. The most interesting singular fact is that histologically the tumors consist of the same connective and non-striated muscle tissues as constitute the normal uterine substance and differ only in their structural arrangement.

IRRADIATION

Soon following the discovery of radium by Madam Curie in 1898 and improved x-ray technic, there was a tremendous change in the treatment of uterine fibroids and it seemed for a time the surgical treatment would become extinct. However, today, in the vast majority of cases it must be acknowledged as the most important and trustworthy of all known methods. It is not the intention of the writer to belittle the value of radium and x-ray in the treatment of uterine myomas, although he is of the opinion they are overestimated by the enthusiasm of many roentgenologists and radium therapists. Obviously, W. J. Mayo clearly stated the sentiment of the surgical profession when he said "Radium must justly be considered in selected cases as a competitor of hysterectomy but it has no comparative standing in cases suited for myomectomy."

CLASSIFICATION OF INDICATIONS FOR OPERATION

In the presence of uterine myoma there are certain definite indications under which surgical intervention should be instituted unless precluded by constitutional diseases or obesity, the presence of which would necessitate a hazardous risk. For the purpose of description they have been

* Read before the Academy of Medicine, Columbus, Ohio, October 14, 1929.

classified with relation to their importance as follows:

1. Tumors with benign or malignant degenerative changes which Noble has classified as follows:⁴

CLASSIFICATION OF DEGENERATIVE CHANGES

| Form of Change | No. Cases | Per Cent |
|---|-----------|----------|
| Hyaline..... | 72 | 3.1 |
| Hyaline with calcareous infiltration..... | 8 | 0.3 |
| Calcareous..... | 39 | 1.7 |
| Myxomatous..... | 89 | 3.4 |
| Cystic..... | 58 | 2.5 |
| Hemorrhagic..... | 13 | 0.57 |
| Necrosis..... | 119 | 4.7 |
| Fatty degeneration..... | 7 | 0.25 |
| Edema..... | 17 | 0.74 |
| Sarcoma..... | 34 | 1.4 |
| Carcinoma corporis..... | 42 | 1.8 |
| Carcinoma cervix..... | 16 | 0.7 |

He finally concluded that these degenerative changes occurred in 62 per cent of fibroma of the uterus. It is unnecessary to mention the importance of early recognition and radical operation in the presence of the last two mentioned conditions, namely sarcoma and carcinoma. Even as early as 1921, Essen Moeller⁵ reported 22 malignancies in 700 fibroid cases, 6 of which were cancer and 16 sarcoma. That sarcomatous degeneration occurs relatively more frequently than is commonly believed by the general medical profession has been proved by Winters⁶ most thorough and definite microscopical findings of 4 per cent. The frequency of carcinoma, which in itself is not a definite degenerative process as it must originate from epithelium, has been proved by Weibel⁷ who reported a series of 1000 uterine myomas in which carcinoma of the fundus was found in 20 cases and Noble⁸ who states that cancer was present in 2.8 per cent of a series of 4880 cases of fibroids collected by him. The cervix was involved in 1.29 per cent and the fundus in 1.05 per cent. Note the reversal of the location of the tumors to that found under ordinary conditions. In the writer's series of 68 uterine fibroids, 3 cases were complicated

by carcinoma of the fundus and 1 by carcinoma of the cervix.

2. Tumors accompanied by inflammation frequently subsequent to degenerative changes involving the tumor itself or infection or disease of the appendages. Cullens, Popow, Virchow, Tait, McDonald and Webster are of the opinion that 50 per cent of all uterine fibroids are accompanied by inflammation of the adnexa. However, as in the case of the hen and the egg, no one seems prone to state definitely whether the tumor resulted from the appendageal inflammation or the appendageal inflammation resulted from the presence and growth of the fibroid. Nevertheless, the presence of the inflammation in association with fibroids is a definite indication for surgical intervention and surgical intervention only, not radium or x-ray.

3. Tumors accompanied by pressure symptoms resulting from impingement on the bladder, ureters, and rectum characterized by irritability of the bladder with frequent, urgent, and painful urination and not infrequently urinary retention, which unrelieved, ultimately terminate in cystitis with bladder wall distention and thickening, hydroureter and hydro-nephrosis with final permanent destruction of the normal kidney substance. Pressure upon the rectum frequently results in constipation, autointoxication and anemia. The tumor or tumors are usually wedged and firmly fixed in the pelvis; however, small intraligamentous tumors are frequently of no little source of disturbance.

4. Tumors 15 cm. in diameter equal to four months' pregnancy or larger should be removed surgically especially in women under forty years of age as irradiation in sufficient amount to cause an appreciable shrinkage in the size of the tumor would result in irreparable damage to the ovaries. In fact, opinion is rapidly becoming established that the effect of irradiation on uterine fibroids is secondary to its effect on the ovaries. Masson states: "Apparently there is little or no decrease in the

size of a tumor after treatment by roentgen rays or radium unless the doses are powerful enough to precipitate the menopause.”⁸

5. Tumors present in sterile women of suitable age with a desire to bear children when other conditions productive of sterility have been eliminated should be removed surgically. Mayo reports 23 pregnancies following myomectomy in 151 married women and Stacy, 28 pregnancies in 203 myomectomized women.

6. Tumors with relation to their position which may be classed as pedunculated and submucous in type, all doubtful cases and rapidly growing tumors, especially those accompanied by hemorrhage unrelieved by other known means.

TYPES OF OPERATIVE PROCEDURE

The surgical procedure necessarily resolves itself into two definite plans, myomectomy, conservative in type, and hysterectomy, radical in type, each of which has proved of equal safety relative to mortality. At the Mayo Clinic extending over a period of five years, 259 myomectomies had been performed with 2 deaths (0.77 per cent) and 1643 hysterectomies with 31 deaths (1.88 per cent).⁹ In 1926 under the caption of “The Safety of Hysterectomy” the writer reported a personal series of 182 hysterectomies with a mortality of 1.07 per cent. Since that report, 74 additional hysterectomies have been performed, increasing the total to 256 with 9 deaths or a mortality rate of 3.51 per cent. An increase in mortality has been noted which is accounted for in the fact that with increasing experience, a feeling for more conservatism in pelvic surgery has developed which naturally relegates the less critical cases to myomectomy, leaving the more critical cases for hysterectomy. Statistics show death following either operation to have resulted from accidental factors in the majority of cases, pulmonary embolism contributing to over 50 per cent of the cases.

Myomectomy like hysterectomy has certain definite indications for its adoption.

However, each case predisposes certain personal status in regard to age, occupation, social and financial position and the desire to bear children. When these deductions have been made, myomectomy may be said to be the operation of choice in the majority of patients under thirty-eight years of age with single or several isolated tumors located in such a position in the uterus that they can be readily shelled out without unreasonable damage to the uterine substance. Especially does this apply to isolated sessile and pedunculated tumors as well as many of the interstitial varieties. The hope of pregnancy and desire to conserve the menstrual function call for conservatism. Bonney successfully removed from the uterus 30 fibroids in one patient by myomectomy. Kelly successfully removed 9 tumors through separate incisions on one patient and 12 tumors in another, and twice removed tumors as large as a man's head by myomectomy.

METHOD OF HYSTERECTOMY

Hysterectomy solicits three methods of procedure, namely, subtotal, total and vaginal, each of which should be determined by definite indications. The uterus should be removed in part in the presence of all fibroid tumors accompanied by hemorrhage or profuse discharge uncontrollable by other means. Total hysterectomy should be performed when definite evidence signifies involvement of the cervix. That total hysterectomy can be performed by competent surgeons as safely as subtotal has been proved by the data of many operators. In a personal series of 256 hysterectomies there were 159 total hysterectomies with 6 deaths (3.64 per cent), 96 subtotal hysterectomies with 3 deaths (3.12 per cent), and one vaginal without mortality.

Upon sufficient evidence of malignant degeneration but one procedure is left to choose from and that is panhysterectomy. At the Mayo Clinic over a period of five years 16 cases of carcinoma of the cervix were accumulated from three to

fifteen years following subtotal hysterectomy for non-malignant growths and 13 cases in which it was impossible to determine the existence of malignancy at the time supravaginal hysterectomy had been performed. Subtotal hysterectomy should be the choice, once the involvement of the cervix has been ruled out, in all cases of uterine myoma complicated by inflammation of the appendages, especially when as a result of severing adhesions the organ would be denuded to such an extent that further adhesions in the pelvis would be inevitable, and in all cases in which removal of the fibroid by myomectomy would necessitate an appreciable sacrifice of uterine substance.

SUMMARY

It is the writer's conclusions that the surgical treatment of fibroids has been too radical; that sound surgical judgment must

be exercised in determining the choice of operation lest one become ultra-conservative which leads to unsatisfactory results; that the value of irradiation has been overestimated and finally, it must be remembered that a patient with fibroids is being operated on and not alone a uterus with fibroids.

AN IMPROVED AIR INJECTION APPARATUS FOR THE INFLATION OF JOINTS*

RICHARD F. BERG, M.D.

NEW YORK, N. Y.

RECENTLY there has been a great deal of work done on the inflation of joints, either of the chronic arthritic or acute purulent types. In the main, this has been carried out by means of the syringe method or by means of more or less cumbersome implements; therefore it was with this idea in mind that an improved method was sought. The first personal attempt was carried out on the Bone and Joint Service of the Boston City Hospital in 1928, and there the cases chosen for the inflation were mainly of the acute gonorrheal type. The results in these were quite encouraging, but it is not the author's idea in writing this paper to bring out the clinical data established in those cases. The purpose of this paper is to present to the profession a very compact and efficient apparatus for the inflation of joints by air.

The advantage of the improved apparatus is, of course, to allow for complete aseptic aspiration of the diseased joint, and secondly to have an absolutely aseptic method of inflating the joint with sterile air, at the desired pressure.

The complete set as shown in Figure 1 consists of a mercury manometer, a sterilizing chamber, a detachable rubber connection, one end of which attaches to the exhaust of the sterilizing chamber, the other end fitted with a two-way adaptor. The adaptor will accommodate the syringe and aspirating needle. Figure 2 shows the detachable portion of the set and is seen to consist of the rubber connection, adaptor, syringe, needle and release valve. This portion is boiled as often as it is used, and if necessary several of these parts can be kept on hand in sterile packets all ready for use.

The manometer, sterilizing chamber and

pressure bulb are mounted on a small detachable metal stand. All parts can easily be taken down and will fit into a very compact case.

Principle of Operation. The principle consists in delivering air to the sterilizing chamber which is constantly governed by the manometric pressure as indicated on the mercury column. The air is bubbled through the sterilizing solution which completely precludes the danger of carrying any particles of dust or contaminated material over into the joint. The exhaust tube of the sterilizing chamber therefore supplies the air in pure form to the sterile rubber tubing and attachment. The pressure is constantly governed and easily controlled by the bulb attached to the manometer. The sterilizing solution used is 70 per cent alcohol.

Technic. The joint to be inflated is scrubbed, shaved and painted with iodine or other suitable skin antiseptic. Sterile sheets are draped around the area to be used and the sterilized unit is then attached to the exhaust of the sterilizing chamber. The syringe and aspirating needle are attached to the threeway adaptor and with the skin previously anesthetized with the aid of novocaine or ethyl chloride, the needle is inserted into the joint cavity. The fluid, if there be any, is then aspirated by means of a 20 c.c. syringe and the specimen kept in a sterile tube for bacteriological examination. When all the fluid has been removed, the two-way cock is turned, thereby opening the channel between the sterilizing air chamber and the aspirating needle, and cutting off the path to the syringe. The air is then slowly forced into the joint by pressure on the bulb in much the same manner as in taking a blood pressure. The joint space is then seen

* Submitted for publication February 17, 1930.

gradually expanding and depending upon the amount of pressure used, will be either soft or quite firm to palpation. Generally

that only the resistant, thickened or adherent synovial membrane will remain in contact with the adjacent tissues. When

FIG. 1. Complete set assembled and ready for use. Sterilizing chamber and manometer attached to a demountable metal stand. All parts fit into a small compact case.

speaking, 40 to 50 mm. of mercury pressure will be easily tolerated by the average

FIG. 2. Boilable parts of set. Release valve allows immediate release of injected air, if so desired.

patient without discomfort. It does not seem that greater pressures are necessary, as under these conditions it will be seen

FIG. 3. Drawings showing needle in joint space. No. 1 shows aspiration to remove fluid, and ascertain that needle is not in blood sinus. No. 2 shows injection of sterile air, with synovial membrane distending.

the desired pressure has been attained, the needle is withdrawn and the punctured wound painted with collodion. An injection usually suffices to keep the surfaces apart for a period of from three to seven days after which time it can be repeated. If another joint is to be injected at the same time, the syringe and aspirating needle together with the rubber connection may be reboiled or another set kept on hand for immediate use. *It is very essential before injecting air that the needle is not in a blood vessel or sinus, as serious results may ensue if air under pressure is injected into open veins.*

Summary. The author has personally used this method on the following types of joint condition:

1. Chronic arthritis with effusion.
2. Acute gonorrheal arthritis.
3. Acute infectious arthritis.
4. Synovial tuberculosis.

5. Hemophiliac joint (1 case only).
6. Postoperative tuberculous synovitis with synovectomy (1 case only).
7. Suggested use on joints immobilized in plaster casts over long periods of time to try to prevent some of the troublesome joint stiffness seen in these cases, reference being made to cases with fractured femurs, etc., in plaster spicas.

The results of these cases seem very promising and interesting, and the data will form the basis of a later paper. It is felt that in presenting this simplified set, that a great many more of the profession

will realize the adaptability of an accurate and simple apparatus in the growing practice of producing pneumoarthrosis in certain pathological joint conditions. The author sincerely hopes that some of the men who are particularly interested in this line of work will offer any suggestion or criticisms they may deem advisable.

The author wishes to express his gratitude to Dr. E. A. Sommer of Portland, Oregon, and to Drs. W. B. Coley, Arthur Krida, Bradley Coley and J. McWhorter, for their kind suggestions and help in this work.

CASE REPORTS

CHRONIC PANOSTITIS*

INVOLVING ATLAS AXIS AND THIRD CERVICAL VERTEBRA

ALFRED J. BUKA, M.D.

PITTSBURGH, PA.

INASMUCH as panostitis of the upper cervical vertebrae is uncommon this report of a fatal case should prove of interest.

A thirty-seven-year-old female, married, had been admitted to the hospital on four occasions within a period of about twenty months.

The only previous noteworthy illnesses had been chicken-pox in childhood and influenza in adult life.

March 26, 1928, first admission to hospital, diagnosis: Neurotic with mitral disease. Throat: "pillars injected, red, tonsils are red, congested, appear infected." Basal metabolism rate, +13. Urine, negative. Wassermann, reaction negative. White blood corpuscles 13, 150; polymorphonuclear 76 per cent, small mononuclears 13 per cent, large mononuclears 8 per cent. Sugar tolerance fasting 102; first hour 308, leucocytes second hour 250, third hour 220, suggesting hyperthyroidism. Gastrointestinal series, negative. Gall bladder normal.

August 14, 1928, second admission, diagnosis: Thyrotoxicosis (infective in origin). Pharynx appeared injected, also left anterior pillar. Throat shows small atrophic tonsils from which cheesy exudate is easily expressed. "If thyroid disturbance exists it is probably on an infective basis from tonsils and gums." B.M.R. +8.

September 8, 1928, consultation and examination by Ear Nose and Throat Department revealed left tonsil submerged, anterior pillars inflamed, considerable caseous material expressed from left tonsil. B.M.R. -6. Impression: "chronic infected tonsils."

October 4, 1928, Tonsillectomy under local anesthesia with much improvement in patient's condition. Weight on admission 91½ lb., on discharge 94 lb. Hemoglobin 75 per cent, R.B.C. 3,890,000. W.B.C. 7200, P.M.N.L. 68 per

cent, S.M. 30 per cent, L.M. 2 per cent. Throat culture, staph. and strep. Sugar tolerance fasting 120: I, 200, II, 205, III, 190.

May 13, 1929, seen in Out-Patient Department, Ear Nose and Throat Clinic, with an acute coryza; complaining of a burning sensation in posterior pharynx. There was some injection, with irritation of the mucous membrane. Lymphoid tissue in upper pole, left tonsillar fossa. Aseptic treatment directed to nose, none to throat.

July 18, 1929, throat painted with silver nitrate 2 per cent. Complained of being afraid to eat because of a choking sensation. Impression appears to be hyperthyroidism, though B.M.R. has always been within normal limits.

July 25, 1929, seen at home suffering with acute lateral pharyngitis which gradually localized with abscess formation over right posterior pillar. Incision with release of pus. Remained in bed at home for one week. Neck began to feel stiff, and throat not so sore.

August 8, 1929, seen in Out-Patient Department, Ear Nose and Throat Clinic, complaining of ears aching, difficulty in swallowing at times, neck feeling rigid. Appears to have lost great deal of weight. There is a discharging opening in right posterior pillar which is much swollen. Neck is held rigidly, some tenderness over muscular insertions. Temperature, 98°F. Pulse, 104. Throat culture: Strep. predominating; also Putrifecans. x-ray of cervical vertebrae with report of "No radiographic evidences of pathology."

August 11, 1929, third admission, diagnosis: Retropharyngeal focal infection giving rise to cervical myositis and fibrositis. Urine, negative. R.B.C. 3,710,000. W.B.C. 10,000; P.M.N.L. 75 per cent, S.M. 14 per cent, L.M. 9 per cent, T.R. 1 per cent, E. 1 per cent. Throat culture, Strep.

August 13, 1929, examination revealed an

* Submitted for publication, February 26, 1930

opening surrounded by pale granulations on the right posterior pharyngeal wall in region of the posterior pillar, discharging thick greenish-yellow pus. The area was swollen, with some stiffness of the neck especially on backward movement; tenderness over back of neck, more marked on left side. Cervical glands not palpable. No tenderness over spine. Impression: "Post-pharyngeal space abscess; vertebral caries?"

August 15, 1929, under local anesthesia, the pharyngeal opening was widened and granulations curetted. Probe went back to spine, but no bare bone was felt.

August 22, 1929, injection around opening a little smoother, with paler cheesy pus still discharging from the sinus. Neck rigidity is perhaps a little less.

August 24, 1929, Esophagoscopy: nothing below cricoid; edema above cricoid with narrowing of esophagus.

September 7, 1929, discharged from hospital to return to Out-Patient Department for diathermy and observation.

September 14, 1929, seen in Out-Patient Department, improving, being treated by physiotherapy.

September 19, 1929, an x-ray with probe inserted in fistulous tract revealed "Rather marked destruction of the upper anterior portion of the body of the third cervical vertebra which was not present on previous examination, (August 8, 1929). The probe inserted through the fistulous tract seen to extend down to this necrotic portion."

September 21, 1929, transferred to Orthopedic Clinic. On examination patient appeared nervous, complained of having a choking sensation for past two years. Presence of a chronic discharging abscess and sinus in right retropharyngeal space would indicate that a long standing pathology exists in that region. The probability of bony involvement was immediately suspected. All efforts at movement of head, painful and very limited. Some muscular rigidity of the anterior muscle groups of the neck. Head held very guardedly. Loss of weight apparent for past two years. Immediate hospitalization recommended.

September 24, 1929, x-ray of cervical vertebrae revealed necrosis previously noted in the third cervical vertebra further advanced with some beginning necrosis in the lower portion of the second cervical vertebra.

When she was referred to the Orthopedic

Department the diagnosis of cervical tuberculosis was made clinically. It was felt that regardless of the type of bone disease the

FIG. 1. Looking down upon atlas, showing marked destruction of anterior arch and extensive erosion of right superior articular surface.

FIG. 2. Looking up upon base of axis, showing erosions.

FIG. 4. Posterior view, showing extensive erosion and ossification between laminae of atlas and axis.

treatment of primary importance would be recumbency with fixation and temporary moderate traction. Because of the many neurological symptoms manifested, e.g.: exophthalmus, nystagmus, light flashes, spots before the eyes, tremor, as well as choking sensation following swallowing of food, enlargement over thyroid and the general imbalance of the sensory nervous system, a consultation was requested with the Neurological Department. The diagnosis, with remarks follow: "T.B. of atlas (Runge? syndrome), T.B. of thyroid (?) or hyperthyroidism. These conditions are usually fatal. Outlook very grave. Only treatment is complete fixation of the head. Morphine sulphate to be used freely." Hg. 75 per cent, R.B.C. 3,950,000. W.B.C. 11,300: P.M.N.L. 78 per cent, S.M. 21 per cent, L.M. 1 per cent. Sputum and throat culture, negative for tubercle bacilli.

During the patient's recumbency the head fixation with traction was carried to the point of tolerance. There were times when it became

necessary to relieve weight suspension because of aggravation of pain which this treatment occasioned. However, after recumbency with

October 29, 1929 she was able to walk about with assistance and after a few days was walking unaided. Patient presented all evi-

FIG. 5. Film taken August 8, 1929, showing no evidence of pathology.

FIG. 6. Film taken September 19, 1929. Probe inserted through fistulous tract is seen to extend down to necrotic third cervical vertebra.

a varied fixed policy of head traction for about six weeks, during which time a normal temperature was established and the general condition of the patient improved, a semi-soft collar was decided upon. To apply this apparatus was a delicate procedure in this instance, because of the danger of disturbance to the suppurating process and a flare up of the bony pathology.

October 17, 1929 a snug and highly fitted collar of felt with plaster-of-Paris reinforcement was placed about the neck. Close upon the application of this collar, although the patient complained about its being tight and limiting the motions of the chin, she admitted she was more comfortable. The general symptoms complained of, pains about the head, vertigo, flashes, spots and blurring of vision, difficulty in swallowing, swelling and pain about the ears, etc., gradually diminished. The patient became more cheerful and began taking on weight. Two days after application of collar, she was able to sit up with support of a back-rest although vertigo, tinnitus and impaired vision were still fleeting disturbing factors.

October 25, 1929, began getting out of bed on wheelchair.

dences of feeling much more comfortable than on admission to the Service and plans for her going home soon were uppermost in her mind. During the course of this treatment patient was constantly swallowing the discharge from the fistulous retropharyngeal opening. She was instructed to expectorate this material whenever possible, and it was no difficulty at any time to obtain pus which was thick and very tenacious in character, sometimes yellowish green in color and often blood-streaked.

November 4, 1929, or thereabout, it was found that the collar support was becoming very loose, that the neck was much smaller, and that even the height of the collar was insufficient to hold the head in the original fixed position. Symptoms such as those complained about on admission began to reappear fleetingly and for increasingly longer periods. It could be seen that the collar was not holding the head sufficiently firm. Because of the increased mobility of the head the collar was elevated with a $\frac{1}{2}$ in. thickness of piano felt which was placed between the lower portion of the collar and the base of the neck as a tem-

porary expedient, until a new collar could be applied. A gradual improvement in her general condition with temperature decreasing and pain diminishing was apparent.

November 12, 1929, or thereabout, a setback from her previously encouraging convalescence set in most rapidly. There was a sudden marked rise in temperature with correspondingly increased pulse and respiration rates. The face became flushed, patient complained of severe headache, pains in ears, dizziness and marked disturbances of vision.

November 14, 1929 in the evening patient developed an alarming condition. It was reported she had raised herself in bed and that the head fell back, as though snapped, when she was in the erect position. In all likelihood the odontoid process of the axis broke away at this time. (At post mortem the axis was found with this process unattached.) When seen by me on this evening the patient was in a comatose state, head firmly fixed, face flushed, pupils dilated and eyes staring vacantly. Her speech was of a mumbling muttering type except when aroused. She was able to give yes or no answers to questions and her sight was not entirely gone. The head was drawn backward, the knees and hips flexed. She gave the appearance of having some central nervous disturbance of serious character.

November 15, 1929 when seen in the morning her condition was grave. She appeared moribund. She had a vacant stare, eyes widely open, pupils dilated with no reflex response to light or accommodation. There was no response to questioning, she mumbled incoherently, upper and lower extremities were flexed, face flushed and expressionless. It was clear there was a marked central disturbance with involvement of the meninges.

November 16, 1929, patient expired.

An autopsy was performed by Dr. K. Yardumian, pathologist of Montefiore Hospital, and his report follows:

The body is that of a white female, about the age of forty, fairly well nourished and well developed. Rigor mortis well set; moderate lividity present at the dependent parts of the body. On general inspection, the neck was found to be surrounded by plaster-of-Paris cast. The head was covered by dark brown hair with a few gray ones in between. There was a decubitus at the posterior part of the occipital region, the size of a silver quarter. The pupils

were evenly dilated. The cornea was slightly opaque. The ears and nose were grossly negative. The muscles of the neck were atrophic.

FIG. 7. Film taken September 25, 1929. Necrosis previously noted in third cervical vertebra is still present and beginning necrosis is now seen in lower portion of body of second cervical, and some rarefaction of body of first cervical vertebra.

Permission for autopsy was authorized to the head and limited portion of the neck.

The usual incision, from ear to ear, was made on the scalp. The cranium was sawed and the brain exposed. The meningeal vessels were dilated. There was a moderate increase of cerebrospinal fluid in the subarachnoid space. The fluid looked rather clear and transparent. On further sectioning, at the posterior fossa of the base of the cranium and below the falx cerebellum, there was a great amount of turbid fluid. The inferior surface of the cerebellum and the pons at the medulla were covered by thick yellowish fibrinous exudate. Smears and cultures were taken from these respective places. The brain was removed as a whole and amputated below the medulla. The anterior margin of the foramen magnum looked eroded and rough and was covered with similar exudate. Posterior incision was made at the angles of the occiput and the neck, and the

first two vertebrae were removed (that is atlas and axis). The two bones were firmly united to each other. No motion could be

FIG. 8. Post-mortem x-ray. Further advance of necrosis of third and second cervical vertebrae, and also necrosis of first cervical.

elicited. The body of the atlas looked rough and rarefied. One condyle looked fairly normal; the other one was slightly eroded. The odontoid process of the axis was completely necrosed. The articular surface was destroyed and was very rough; portions were easily pulled away and ragged. It was rarefied and disintegrated. No evidence of thickening or healing process found. No caseation present. The body of the atlas showed similar destructive changes. The periosteum was denuded. The third cervical was palpated at its position, but not removed. The body of it was rough, necrotic and rarefied. Numerous smears and cultures were taken from those necrotic areas.

Through the same incision, an attempt was made to remove pieces of thyroid gland. Extreme care was taken not to disfigure the body; therefore the incision was closed without further exploration.

Finger introduced through the mouth to nasopharynx at the superior posterior angle near to the center showed a sinus leading to the vertebrae of the neck. A large amount of purulent exudate ran out freely.

Microscopical Studies: Numerous smears

were stained for acid-fast organisms and proved negative. Cultures from meningeal exudates from various necrosed bones proved a growth of organisms of which staphylococcus pyogenus aureus predominated. Other organisms were common flora of nasopharynx, such as diphtheroidal bacilli, few streptococci, pneumococci, etc.

Pieces of bones were removed from the odontoid process of the axis and the body of the atlas was decalcified in 10 per cent nitric acid solution, sectioned and stained.

The microscopical picture of the bone is as follows:

Marked rarefaction and decalcification of the body; intense leucotic infiltration both polymononuclear and mononuclear type.

No attempt of regeneration and new bone formation is present.

No evidence of caseation of tubercular reaction seen. Also acid-fast stains disproved presence of any such organisms.

Diagnosis: Chronic panostitis involving bodies of the first, second, and third cervical vertebrae.

Terminal purulent meningitis involving the base of the cerebellum pons and medulla (staphylococcus pyogenus aureus predominating and few of the designated flora of the nasopharynx).

X-ray examinations and reports by Dr. Maurice F. Goldsmith, roentgenologist, Montefiore Hospital.

It is interesting to see how really far necrosis of the cervical vertebrae advanced in this case. An heroic effort had been made by Nature to overcome this condition and the inability to fully fix this effort at ankylosis resulted in a meningeal involvement. The first, second and third vertebrae were all involved in this extensive process of bony necrosis and the brain involvement certainly exceeded expectations.

An otitis of any of the cervical vertebrae, more especially the upper cervicals, presents commonly a discouraging picture. This is further manifested after it has progressed into the chronic stage. An acute involvement of this type frequently responds favorably to treatment by free opening for drainage of the abscess, permitting same to repair from within outward. Fixation in such cases is mandatory, and is best obtained by head traction and weights at the outset to overcome spasm of the cervical musculature. These

muscles are in rigidity and spasm because of the effort of Nature to immobilize the vertebral bones involved. So long as drainage takes place from a sinus, whether retropharyngeal or postcervical, there remains nothing more to do beyond immobilization of bones of the diseased area. Further surgical interference is ill-advised. When the muscle spasm of the groups holding the head in rigidity has been overcome a proper fixation collar which rests directly upon the mid-clavicular region and base of neck is adequate support for the head. With such a collar the patient may be considered an ambulatory case. However, it should be realized that the swelling occasioned from the infiltration of such an inflammatory process and the infective materials in the soft structures about the involved vertebrae may cause considerable thickening of the neck. In such circumstances, what may appear as a tight-fitting collar at the outset will become very loose in the course of drainage of pus through an established sinus. The inflamed and infiltrated soft structures endeavor to assume their normal state. Therefore, the collar must again be adjusted for closer fitting from time to time to the neck of lessened thickness. Thus, there is further endeavor to prevent undue mobilization, with its consequent destruction from irritation, which would occasion a flare-up of the whole process with dire consequences.

In conclusion it is interesting to note that in cases of extensive necrotic cervical panostitis little remains to be done beyond fixation of the head and neck and expectancy from drainage obtained through any location whether retropharyngeal or postcervical. Ideally surface drainage is preferred to that of the oral route. Nothing

can be expected from drainage alone. From fixation much may be hoped for even though drainage is not yet established. Then, too, there is always the question of doubt as to type of infection in the cervical region. It may be tubercular and operation for evacuation of pus would be contraindicated. Whereas, when abscess formation has established itself, it can be readily determined whether same is non-tubercular. Opening for drainage when imperative might take place in the retropharyngeal region, but most certainly should not be the point of election for same if the postcervical region is available.

The diagnosis of tuberculosis of the cervical vertebrae is not amiss in a case of this sort. One would almost invariably consider this form of infection first. However, in any type of panostitis, the treatment would always be the same, namely: fixation and drainage. We were not convinced up to the last point of demonstration at autopsy as to the type of organism underlying the initial phase of the case. When finally the *Bacillus tuberculosis* was eliminated and it was established that the infection was from without (oral cavity), in all probability of recent date, the case was considered of sufficient interest for presentation. The predominating organism in the lesion was, as noted in the pathological report, *Staphylococcus pyogenes aureus*.

An expression of gratitude is extended Drs. M. F. Goldsmith and K. Yardumian for their helpful cooperation in preparing this presentation.

ACUTE PANCREATITIS

WITH A REPORT OF TWELVE CASES*

WILLIS M. WEEDEN, M.D.

NEW YORK

UNDER this heading are included (1) acute hemorrhagic, (2) acute gangrenous and (3) acute suppurative pancreatitis. It is generally considered that these are merely various phases of the same disease and may follow one another or may occur concurrently in different parts of the pancreas in the same individual.

Acute pancreatitis is one of the tragic diseases of surgery. With sudden onset and rapid development it progresses all too frequently to a fatal outcome. Its etiology is obscure, its diagnosis difficult and its treatment unsatisfactory.

There has been much work done and many articles written on the various theories as to how infection reaches the pancreas. Deaver, Sweet, Judd and Mann have been the principal proponents of the lymphatic theory of infection, while Archibald and Kaufmann have carried out many experiments which would seem to show that infection takes place through the ducts. Superficially it would appear as if these two theories were diametrically opposed to each other and in fact their advocates seem, to some extent, to take such a view. Careful study of their various reports, however, does not necessarily lead to that conclusion. The adherents of the lymphatic theory are talking in the main about chronic pancreatitis which seems to be an entirely different condition and much more common than acute pancreatitis. That they are entirely different is pointed out by Sweet¹ who says "Chronic Pancreatitis equals infection, Acute Pancreatitis equals liberation of trypsin, by infection or trauma." Deaver² says "Extension of inflammation of the gall bladder mainly by way of the lymphatics gives rise to lymphadenitis

along the course of the common duct and its lymphatics in the right free border of the gastrohepatic omentum, and to a peripancreatic lymphagitis and lymph adenitis with enlargement and hardening of the adjacent portion of the pancreas itself." He cites several cases where this occurred not only from an inflamed gall bladder but also following an acute inflammation of the appendix. But he makes no claim to having seen anything more acute than a lymphangitis of the pancreas following such conditions. In the same article Sweet,² after discussing from an embryological standpoint the various relations possible between the emptying of the common and pancreatic ducts says:

Infection of regional lymph nodes might well cause a simple damming back of lymph with aseptic swelling of the interstitial tissue, later organization and increased interstitial tissue, which is precisely the picture of *chronic* pancreatitis. And Cases of chronic pancreatitis do not show clinical symptoms which might be ascribed to transitory attacks of limited acute pancreatitis with later transformation of the degenerated acini into sclerosed areas.

Mann's experiments as reported by Judd³ consisted of injecting bile into the pancreas with a syringe at a pressure of 500 mm. or less, he having previously ascertained that the normal pressure of the liver and the contraction of the gall bladder combined did not exceed 350 mm.; and was not able to produce an acute pancreatitis. Archibald⁴ doing the same experiment but using infected bile produced a typical necrosis of the pancreas. In summing up Judd³ says:

If Mann's conclusions regarding the bile factor in the etiology of pancreatitis are cor-

* Submitted for publication January 9, 1930.

rect, it would seem that, in most cases at least, we must search elsewhere for the cause. It will most likely be found, as Deaver says, in the extension of infection to the pancreas through the lymph channels. It is possible that infection in cases of cholecystitis changes the bile so that it readily causes trouble in the pancreas.

Nordmann⁵ found that normal bile entered the pancreatic duct without doing any particular harm while infected bile caused acute pancreatitis. Mann and Giordano⁶ and Judd³ have shown that in only 3.5 to 4.5 per cent of bodies examined, obstruction at the ampulla of Vater either by a stone obstructing the ampulla or by spasm of the muscle of Oddi, would convert the common bile duct and the duct of Wirsung into one continuous passage and so permit passage of bile into the pancreas. If one accepts the theory of infection through the ducts this fact which has been used as an argument against the theory might tend to explain the relative rarity of acute pancreatitis. Kaufmann's⁷ experiments consisted of infecting the lymphatics around the gall bladder, around the ducts and around the pancreas itself. He succeeded in causing a lymphangitis and a lymphadenitis and by contiguity to infected nodes small infected areas in the pancreas but did not produce an acute pancreatitis. He, therefore, because of these results and because he cannot believe that lymph would actually flow backward into the pancreas, concludes that "the clinical proof which has always been based on the assumption that experimentally and anatomically, the lymphatic route of infection was possible, must of necessity be regarded as non-existing." But here again we can find no incompatibility with Sweet's theory as outlined above. A localized area of pancreatic necrosis may be caused by contiguity from infected nodes, or by contact with a duodenal or gastric ulcer. A possible etiology by a hematogenous route has been suggested by some authors. Hunt⁸ asks why since the parotids are known to be

subject to specific infection, the same could not be true of the pancreas.

Acute pancreatitis occurs as a rule in middle-aged individuals, especially in those who are overweight. It is slightly more common in men than in women. Alcoholism and diseases of the biliary system are considered contributory causes.

Correct diagnosis is only occasionally made before operation. This is undoubtedly due to the fact that the disease is comparatively so rare in occurrence. The attack is ushered in by a sudden terrific pain in the epigastrium. According to Moynihan,⁹ "of all the pains the human body can suffer, this is by far the worst." It may radiate to the back or either shoulder, especially the left. As a rule it is attended by marked collapse with rapid thready pulse, shallow breathing with characteristic dyspnea and fall in temperature. The temperature will rise on the second or third day. Vomiting generally occurs and is interspersed with retching and hiccough. Jaundice may or may not occur.

Examination of the abdomen shows moderate distention with tenderness and rigidity especially of the epigastrium. Tenderness in the gall bladder region extending beyond the midline is very suggestive. There occasionally is bulging of the flanks and the presence of fluid may be detected. Rarely it is possible to feel a mass in the region of the pancreas. A diagnosis of high intestinal obstruction or perforated ulcer is most apt to be made. In intestinal obstruction the pain is not apt to be as severe nor is collapse as marked. The vomiting occurs with little or no nausea, may be projectile in character and if long continued may become fecal in type. In perforated ulcer, a history of previous ulcer symptoms, obtained in about 50 per cent of cases, is of value. Tenderness and the rigidity which is generally more severe extend over the whole abdomen and are not more marked in the epigastrium than elsewhere. The presence of air under the diaphragm as

shown by x-ray would clinch the diagnosis of a perforated viscus. Lowe's mydriatic test has been of value in some cases. This consists of putting four drops of 1/1000 adrenalin in one eye, repeat in five minutes and examine at the end of thirty minutes. Dilatation of the pupil is a positive test. Glycosuria is not an infrequent finding and if it can be determined to be of recent origin, may be helpful in making the diagnosis.

Treatment consists of early operation. When the abdomen is opened, the presence of blood-stained fluid and areas of fat necrosis makes the diagnosis. However, these latter may be absent or may be confined to the root of the mesentery in the immediate neighborhood where they should be carefully looked for. In the more advanced cases the pancreas is felt to be enlarged with a tense capsule and depending upon the stage of the disease, there may be areas of softening or fluctuation. Operative procedures vary, depending upon the pathology present and the condition of the patient. In the very early cases where there is no pus or fluid present cholecystectomy seems to be sufficient. The general practice at present is to drain the biliary system either by means of a cholecystostomy or if the patient will stand a cholecystectomy by a tube in the common duct. All the fluid in the peritoneal cavity should be removed by suction and a drain placed to the capsule of the pancreas. If there is definite softening of the pancreas or abscess formation, the capsule should be split and a drain placed into the pancreas itself. In the very severe cases this is all that should be done as in these cases drainage is the essential need. Any free necrotic material should be removed, though none should be forcibly torn away due to the great danger of hemorrhage. The drain in the gall bladder or duct should be left in situ for two weeks or longer, but the drain to or into the pancreas can be loosened at the end of three or four days and removed as soon as the discharge diminishes.

Bailey¹⁰ suggests the use of an ointment containing 2 per cent of hydrochloric acid to prevent the digestion of skin around the wound by the pancreatic ferment. Errors in carbohydrate metabolism should be carefully watched for and suitably treated. As hepatic insufficiency and a depletion of glycogen reserve are likely to be present, glucose infusions should be given both before and after the operation. Recurrence of the disease may take place after an apparent cure as is illustrated by one of our cases (No. 6).

Following is a summary of twelve cases operated on the First (Cornell) Surgical Division of the New York Hospital since 1914.

1. Male, aged thirty-nine. Dull pain in epigastrium for one week, vomiting for three days. No bowel movement for three days. Moderately alcoholic. Large man, cyanotic, diffuse rigidity and tenderness of abdomen most marked in epigastrium. Temperature 101.6°F; urine, no sugar. Operation, sweet-smelling turbid oily fluid in peritoneum. No fat necrosis. Pancreas enlarged and indurated. Cigarette drain to pancreas. Died sixteen hours postoperative. Autopsy showed multiple abscesses.

2. Male, aged thirty-two. Sharp cramp-like pains in lower abdomen for four days. Nausea but no vomiting. No bowel movement in three days. Obese man, distended abdomen, rigid in right upper quadrant, tender to left of umbilicus. Temperature 102°F. Operation turbid serum especially in lesser sac. Multiple hemorrhagic areas. Pancreas swollen. No definite fat necrosis. Lesser sac and gall bladder drained. Died five hours postoperative.

3. Male, aged forty-five. Pain in abdomen for one month, severe for eighteen hours. Vomited once, moderate belching. Marked rigidity and tenderness on right side. Temperature 100°F. White blood count 1800, 87 per cent. Operation, small amount of bloody fluid, fat necrosis. Pancreas necrotic, hemorrhagic and soft. Drain to pancreas. Left hospital cured on eleventh postoperative day.

4. Male, aged fifty-seven. Pain in epigastrium with vomiting for two days. Indigestion for one year. Obese man, distended abdomen, fluid wave present, tenderness in epigastrium,

markedly cyanotic. Operation, large amount bloody fluid, fat necrosis, pancreas large, swollen, indurated. Temperature 101°F. Died on operating table. Was operated at family's insistence though moribund on admission.

5. Male, aged forty-three. Pain in epigastrium for six days. Well nourished. Abdomen hard and boardlike, tender all over. Temperature 97°F. White blood count 7600, 72 per cent. Operation, oedematous gelatinous infiltration of peritoneum. Pancreas swollen and soft. No fat necrosis. Cholecystostomy. One stone present. Home on thirty-third day.

6. Male, aged forty-one. Epigastric pain for two days. Vomited several times. No bowel movements for two days. Two previous attacks. Moderate distention, tenderness all over, especially right upper quadrant. Temperature 101.6°F. Blood count 14000, 78 per cent. Operation, small amount straw colored fluid. Spots of fat necrosis. Large hemorrhagic mass head of pancreas. Gall bladder normal. Cholecystostomy and drain into mass of pancreas. Discharged on seventeenth postoperative day. Readmitted thirty-seven days after discharge. Had been well for four weeks. Similar symptoms and signs. Operation showed pancreas two and a half times normal size. No fat necrosis. Gall bladder and pancreas again drained. Died first postoperative day.

7. Female, aged fifty-three. Severe pain right upper quadrant for two months; had had it at intervals for eleven years. Obese, tender across center of epigastrium. Temperature 103.6°F. Blood count 17,200, 84 per cent. Operation, moderately distended gall bladder containing stones. Pancreas enlarged throughout. Fat necrosis present. Mass in upper surface of pancreas contained 1 oz. of thick pus. Some bleeding. Pancreas packed. Gall bladder drained. Died third postoperative day.

8. Female, aged twenty-eight. Sharp pain left upper quadrant for eight days. Nausea and vomiting for two days. Mass right side, tenderness, no rigidity. Temperature 100–102°F. Blood count 15,000, 92 per cent. Operation, whole pancreas acutely inflamed, fat necrosis. Gall bladder small, infiltrated. No stones. Gall bladder drained. No drainage of pancreas. Ten weeks later a pancreatic abscess was drained. Died sixteen hours postoperative.

9. Female, aged thirty-seven. Epigastric pain for three days. Vomited. Similar attacks

for six years. Obese, tenderness and rigidity in right upper quadrant. Temperature 100–102°F. Blood count 10,500, 78 per cent. Operation, cholecystostomy. Fat necrosis throughout. Hemorrhagic areas in body and tail of pancreas. Reoperated for secondary hemorrhage two days later. Died.

10. Female, aged twenty-six. Operated eighteen months before for acute cholelithiasis. Pain in right upper quadrant and epigastrium for three days. Vomiting. Tenderness and rigidity in right upper quadrant. Temperature 101–102°F. Blood count 17,800, 92 per cent. Operated, stone removed from common duct, pancreas swollen. No fat necrosis. Duct drained. Discharged cured four weeks later.

11. Female, aged sixty. Pain in right upper quadrant, back and right shoulder for four days. Vomited. Similar attack five years before. Distended abdomen, contained fluid. Rigid in upper part. Tender. Temperature 101°F. Blood count 10,400, 84 per cent. Operation, pancreas enormously enlarged, fat necrosis. Gall bladder contained stones. Gall bladder and pancreas drained. Died thirtieth postoperative day. Autopsy showed pancreas to be largely destroyed.

12. Male, aged forty-four. Abdominal cramps, nausea and vomiting for twenty-four hours. Abdomen full and distended, rigid and tender on right side. Temperature 101–102°F. Blood count 15,150, 87 per cent. Operation, pancreas swollen and indurated. Fat necrosis and blood-stained fluid present. Drain placed to pancreas. Discharged cured on seventy-fifth day.

Of 12 cases 7 were males and 5 females. There were 8 deaths, a mortality of 66.66 per cent.

It would seem from these cases that earlier diagnosis and treatment of gall bladder disease might prevent the development of pancreatitis in certain cases.

I desire to express my appreciation to Dr. Charles L. Gibson for permission to publish these cases all of which were operated in his services at The New York Hospital.

SOLITARY CYST OF THE KIDNEY WITH RESECTION*

GEORGE F. CAHILL, M.D., F.A.C.S.

NEW YORK

LARGE, single or solitary cysts of the kidney are of sufficient frequency to find reports on one or several cases in medical literature every year. The usual recommendation of treatment in the textbooks and the literature has been: resection of the cyst. However, nephrectomy has been the procedure in the larger proportion of cases reported in spite of recommendation. I have seen 14 of these cases, 7 in the past year, 4 of which were personally operated upon by me. Of all these cases only 1 on the operating table apparently had the possibility of a successful removal. In some instances the cases had cysts so large that the kidney itself was merely a thinned-out capsule of renal tissue, so to speak, attached to the outer surface of a large cyst. In other cases the cyst occupied the center of the kidney, with an upper pole and lower pole of renal tissue so widely separated, and the cyst itself so closely attached to the pelvis in the center, that a resection of the cyst, and a reunion of the two widely separated portions of the kidney seemed very difficult, if not impossible of accomplishment without leaving a permanent renal sinus and the possibility of an ultimate nephrectomy. In these 14 cases all were nephrectomized except one.

The resected case is as follows:

G. O. P., a physician, fifty-four years old, seen on July 22, 1929, complaining of pain

in the right side of the abdomen, radiating to his right testis. He had had a similar pain three years previously occurring on his left side, followed by hematuria. At that time the pain was attributed to a renal or ureteral calculus, but none was passed and none found on x-ray. X-ray at that time showed very large irregularly shaped kidneys, and a tentative diagnosis of polycystic kidneys was made. As a result he lessened his activities and gained 30 lb. in weight. After a year he became afflicted with dizziness and hypertension. A return to active work and reduction in weight brought his blood pressure down and relieved his dizziness.

When seen the patient was a stout, sturdy man, normal except for some tenderness in his right flank and a large mass, apparently the right kidney. The urine was normal.

Cystoscopic examination on July 24 revealed a normal bladder and urethra. Both ureters were easily catheterized to the kidneys. Clear urine was obtained from both sides, the flow from the left being twice that from the right in the same time. Indigo carmine appeared from the left kidney in three minutes and from the right in three and one-half minutes. In ten minutes the concentration from the left kidney was twice that from the right.

Bilateral pyelograms were done and showed a right kidney high up, with a slightly deformed pelvis and a round smooth mass below, evidently the lower pole of the kidney. The left kidney showed a large upper pole with an irregular cavity in the pole communicating with the pelvis.

Diagnosis was made of a large solitary cyst of the lower pole of the right kidney and a

* Read before the Section of Genito-Urinary Surgery, N. Y. Academy of Medicine, December 18, 1929.

smaller cyst of the upper pole of the left kidney ruptured into the pelvis.

Operation was performed on July 25 and a large solitary cyst of the right kidney was removed by resection of the lower half of the kidney. The bleeding was profuse but was controlled by cross mattress sutures. The cut end of the kidney was covered by a thick flat pad of the lower part of the fatty capsule. A cigarette drain was placed outside of the fat and the wound closed. The patient had an uninterrupted recovery, the wound discharging a moderate amount of serosanguineous fluid. He was discharged on the fourteenth day.

The patient was apparently normal until the seventeenth day when following exercise and straining he had pain in his right side. This was followed by a chill and high fever, with passing of cloudy, burning urine.

Patient was readmitted to hospital on August 15 and the wound opened and several ounces of pus evacuated. The wound then drained freely of urine, followed by a recession of temperature. He passed urine containing pus and liquid fat. The fat would collect and harden on top of his urine. Wound was revised on September 1 and again on September 19 when his kidney was examined. At that time the fat pad over the lower renal pole had practically disappeared. The wound then rapidly closed up. With the administration of methylene blue by mouth, the wound coloration ceased in ten days following the last revision.

Cystoscopic examination on October 1 showed that his right kidney secreted a few pus cells, 0.8 gm. of urea per liter and had an indigo carmine appearance time of three minutes and equal with the left output in ten minutes. His left kidney was free from pus and secreted 0.6 gm. urea per liter. Pyelograms were not done at this time because of the risk of reopening the healed renal sinus.

In history this case was seen to fit the average. The cysts usually are silent and only discovered by accident although at times they may give rise to pain. The discovery of these cysts were by examination and x-ray. The pyelograms were characteristic. In studying these cases we have brought out that there is a peculiar clubbing and shape to the calyces; that the cyst is usually round and that the outline is clear, sharp, distinct and at

times almost capsular in density of outline; that the outline of the kidney tissue is distinct from the cyst, of a different

FIG. 1.

density, and at times can be definitely made out through the cyst. These findings are not those found in tumor.

This case was unusual in that it was the first in a fair number that had the aspect of having a fair chance in resection. Moreover there was a cyst on his other kidney which introduced the additional factor of conservation of the right kidney. In resection the kidney tissue was not cut straight but was beveled into the kidney in the shape of the cyst. This undoubtedly left cut renal tubules that did not communicate with the pelvis after the resection. They must have secreted urine under the fat flap and gradually necrosed it, and have broken down into the pelvis, forming an abscess at the lower pole. The cyst on the left kidney was silent and the kidney apparently normal, which has given rise

to the idea that when next we encounter a non-removable solitary cyst, we open the cyst into the pelvis or calyx through pyelotomy incision and then plicate the cyst. We have tried stripping these cysts out of the kidney in the laboratory, as we

strip an ovarian or any other cyst, but have found it exceedingly difficult to do so without tearing the cyst to pieces. In the resection we agree that it is best to cut straight through renal tissue well away from the cyst.

MECHANICAL APPENDICITIS*

PAUL W. GREELEY, M.D.

WINNETKA, ILLINOIS

NUMEROUS foreign materials are frequently reported as causing appendicitis. Most often the oxyuris

FIG. 1.

vermiformis, other intestinal parasites, cornflower and grape seeds, cholesterol calculi, shot, pins, etc., are the etiological factors. Fecal concretions are very common but recently I have encountered one of unusual dimensions causing an unusual type of pathology.

Mrs. N. D. gave a history of several attacks of pain in the right lower quadrant over a period of two years. The present attack had been in progress about twenty-four hours when

I first saw her. She described the pain as coming in waves, or intermittent in character with no definite time relation between the crest of each sensation. At the height, the pain would make her nauseated, but she did not vomit. Examination revealed a definite tenderness and rigidity of the muscles of the right lower quadrant. Vaginal examination showed nothing more. The pulse and temperature were normal and the white blood cell count 10,500.

A diagnosis of recurrent appendicitis was made and owing to the patient's discomfort, an immediate operation was advised. A right paramedian incision was made. A very large, gray-walled appendix was found. It was the size of a man's thumb and abruptly tapered at the base. It was removed by the usual ligation and purse-string inversion method. The patient made an uneventful recovery and has had no recurrence of the pain since her operation.

The pathological examination revealed that the lumen of the appendix contained one enormous fecalith, measuring 7.4 cm. long, by 2.0 cm. in diameter. The wall of the appendix showed very little change, except for some edema.

Of special interest was the size of the fecalith with such a small degree of associated inflammatory reaction, and also the apparent movements of the fecalith which undoubtedly caused the patient's pain, since it was too large to force its way into the cecum.

The American Journal of Surgery is truly independent and enters into no "entangling alliances." It publishes many papers read before the leading surgical societies of the Country, but it is *not* "the official organ" of any organization. Every manuscript is selected by the editors, as worthy of publication—nothing is published merely because "it was read at the meeting."

POSTOPERATIVE PULMONARY EMBOLISM AND THE REVIVAL OF ARTERIAL EMBOLECTOMY AND THE TRENDLENBURG OPERATION IN SCANDINAVIA AND GERMANY

THE presence in this country of Drs. Gunnar Nystrom, of Upsala and K. H. Giertz, of Stockholm, and the contribution of their personal experiences to the proceedings of The American Surgical Association at its recent meeting in Philadelphia bring to mind the debt of the profession to the Scandinavian surgeons for their initiative and success in the surgical treatment of postoperative pulmonary embolism and the thrombo-embolic obstructions of the peripheral arteries. In fact, the operation of embolectomy for the extraction of obstructing clots from the blood vessels has become a specialty which is a distinctive and almost

unique feature of Scandinavian surgery. The numerous scientific contributions of the Swedish surgeons and their unusual experience in the surgical treatment of these thrombo-embolic complications have served to rehabilitate and revive the practice of embolectomy, which up to fifteen years ago gave little promise of the limb and life-saving value which they have since given it.

To those who are at all acquainted with the history of Scandinavian surgery, including Sweden, Denmark, Norway and Finland in this designation, the great impetus given by the surgeons of these northern countries to vascular surgery, particularly in its thrombo-

embolic relations, their activities and their recent achievements are not surprising. It would seem that this is something of a tradition with them which has been handed from the older to the younger generation as a national characteristic, to be cultivated and perpetuated as a splendid inheritance.

It would be impossible to do justice to the long list of Scandinavian surgeons who since the days of the great Danish pathologist Panum, of Copenhagen, have enriched the literature on thrombosis and embolism in all its complex phases by their notable and, in many instances, epochal contributions. Let us not forget that it was Panum who, next to Virchow, in the fifth decade of the last century, developed and expanded the concept of embolism in a series of experimental researches that have remained fundamental and classical to this day.

In later years, Sweden has taken the lead in this specialty. For instance, the collective statistical studies on postoperative pulmonary embolism contributed by G. Petrén of Lund in 1913 constitute an outstanding landmark in the history of this subject. In this masterly essay Petrén surveyed and summarized all the experience that had accumulated on pulmonary embolism as a surgical complication up to the time of its publication. In this he laid the foundation for the differential index of incidence of this formidable complication as it appears after operations on different organs and regions, at different ages and in various diseases, and it is Petrén's work which has served as a statistical model ever since. Of course, the names of Lennander, the great master of Upsala, of Borelius, of Axel Key and Retzius of Bull, of Nicolaysen, of Hansen, of Bauer, of Key and of Fähræus and Jacobæus (in cognate lines) and of so many other medical representatives of the great Scandinavian family are familiar to the readers of the *Acta Chirurgica Scandinavica* as eminent contributors to the knowledge and literature of this special field.

It was reserved, however, for the surgeons of the present and rising generation to crown the labors of the pioneers by attaining the highest peak of surgical success as we see exhibited in the achievements of the last few years.

There are two phases of embolectomy that the Swedish surgeons have especially developed. One is the dramatic and heroic

operation that Trendelenburg, of Leipzig, devised and first applied in 1908, twenty-two years ago, for the extraction of massive obstructing emboli of the pulmonary artery which, with increasing frequency, contribute to postoperative morbidity and mortality; and the other is the operation of embolectomy for the removal of obliterating clots in the peripheral arteries. In both of these procedures the Scandinavian surgeons have set an example that is now serving as a stimulus and encouragement to the surgeons of other countries to repeat their performances. According to Prof. Einar Key, of Stockholm, himself the foremost exponent of the surgery of the peripheral arterial emboli, 216 embolectomies for the removal of clots in the main surgical arteries, including 11 for clots in the abdominal aorta, had been recorded in the world literature up to 1929, and of these, 146 or practically 68 per cent had been performed by the Scandinavian surgeons, Key himself having contributed 15 of these experiences with 8 recoveries, including one successful aortic embolectomy. When we remember that the first embolectomy was performed by Ssbanejew in 1895, thirty-five years ago, and that during the years that followed (to 1911) only 11 embolectomies or thrombectomies, as they were then called, had been recorded in the literature, that up to that time only one patient had recovered (Lahey, Boston), and that the number of recorded operations has since increased to 205, with 146 of these to the credit of the Scandinavian surgeons, we have good reason to believe that this operation has become a specialty in their hands. This fact is emphasized by Pemberton's (Mayo Clinic) statement that up to 1927 only 20 embolectomies had been recorded in the United States, Canada and Great Britain.

The success of the Scandinavian methods is not due solely to their excellent technic, which is practically the same as that laid down by Carrel for arteriorrhaphy, with the free use of sodium citrate solution as an anti-coagulant, but it is in their alertness

in diagnosis and in their promptness to act on the diagnosis that they excel. Their experience has shown that an embolectomy has infinitely better chances for success when performed within the first ten hours and that beyond this time the recurrence of the clot is almost certain and the damage done to the peripheral circulation is irremediable. This is particularly true of the infectious emboli which are thrown out of the heart in septic endocarditis and other infectious diseases in which the embolus is the carrier of a microbial colony that sets up an endarteritis at the seat of embolic obstruction. When the operation is performed within a few hours after the artery has been obstructed, the permanent restoration of the circulation may be expected in as many as 50 per cent of the cases. The graver conditions in which the deobstruction of the arteries is performed in patients suffering from advanced endocarditis and as complications of other systemic infections and cardiovascular diseases, add greatly to the credit of our Scandinavian colleagues for their remarkable success (34 per cent recoveries in 135 operations performed within the first ten hours, Key).

But even more closely related to the postoperative complications that at present engage our attention is the encouragement that we derive from the experience and courageous enterprise of the Scandinavian surgeons in attacking the far more serious and forbidding problem of the acute massive and fatal emboli of the pulmonary artery.

In this performance they share the honors of a great surgical advance with their German colleagues who have persevered in the seemingly cheerless path laid out by Trendelenburg in 1908. Up to 1924, 20 cases of Trendelenburg's operation had been reported in the literature, but it is probable that other unsuccessful attempts had been made which did not find their way to the medical press. All the cases reported up to that time ended

fatally during or shortly after the operation. The longest survival was Krüger's patient who lived five and a half days after the operation, when death occurred from a secondary empyema. Since 1924, a very decided change in the prospects of this operation has occurred and now the efforts of the bold pioneers have at last been rewarded by success. Since 1924, 7 successful Trendelenburg operations have been reported, one by Kirschner in 1924, one by Meyer of Berlin in 1927, two by Giertz and Crafoord of Stockholm in 1927, and in the same year another by Nystrom of Upsala. Two other patients were operated on by Nystrom between 1927 and 1928. One of these survived the operation thirty hours, and the other five hours. All these patients were *in extremis* when operated on and therefore the seven recoveries were virtually so many resurrections.

Performance of these operations has taught many valuable lessons; among these is the fact, ascertained by Trendelenburg and since confirmed by more accurate observations, that death does not occur instantly with the onset of the first symptoms as formerly believed. Of 20 cases that came under the observation of Giertz and Crafoord in which the time between the first symptoms of the attack and death was recorded, in only 3 did death occur in less than ten minutes, which is, theoretically at least, sufficient time for a trained surgeon in a well-organized hospital to perform the operation. That no more than 3 patients were actually operated upon is due, as these authors state, mostly to the traditional fear of the operation, the only one that can give hope to save life. In some cases the age, obesity of the patient and other existing complications (pneumonia, cardiovascular diseases, etc.) or previous minor attacks, restrained the surgeons from operating.

Another lesson taught by these experiences is the tolerance of the brain and medulla to a suppression of the circulation and respiration for a much longer period than was at one time deemed possible in

view of previous experimental evidence. L  wen and Sievers had set the time limit of survival after total occlusion of the pulmonary artery to two and a half minutes, which in rabbits could be experimentally prolonged by artificial respiration, oxygen and adrenalin, to seven or eight minutes. Trendelenburg had estimated forty-five seconds as the longest time for survival after a total occlusion of the pulmonary artery in the human subject. In Nystrom's cases the circulation was cut off sixty, sixty-five and, in the patient who recovered permanently, one hundred and four seconds. In Giertz and Crafoord's cases the constrictor was kept on the pulmonary artery for forty-five and sixty-one seconds, the whole procedure taking not more than six minutes (Crafoord).

The operation is usually performed without anesthesia, as the majority of patients become unconscious shortly after the attack. None of the patients showed signs of residual postoperative brain lesions when consciousness returned in from fifteen minutes to six hours after the operations, despite the prolonged suspension of the circulation and respiration. A successful Trendelenburg operation leaves no secondary cardiac or pulmonary lesions and the patients after recovery have remained in perfect health for years (Kirschner's patient over four years).

The operation seems to have gained full acceptance in Europe, particularly in Sweden and Germany where it is a regularly standardized procedure.

The operation has been much improved by Prof. A. W. Meyer, of Berlin, who recently visited the United States. He insisted on the importance of avoiding the pleura to prevent the collapse of the lungs from pneumothorax, a particularly serious complication in these circumstances and one which undoubtedly contributed to the mortality following the earlier operations performed by the original Trendelenburg method. He also allowed the pulmonary circulation to be reestablished while operating by resorting to

intermittent partial occlusion of the pulmonary artery. He modified the Trendelenburg instruments, and strikingly demonstrated the great value of adrenalin injections into the aorta and of the inhalations of CO₂ and oxygen mixture as a powerful respiratory stimulant at the critical moment when the respiration is arrested. A suction apparatus, which need not be of the Trendelenburg model, is essential and is of incalculable value in the extraction of the clot. The instruments required are in reality very simple and can be found or improvised in any well-equipped hospital. However, a Trendelenburg outfit modified by Meyer is desirable but not essential for the purpose. What is more important is that the surgeon who may be called to perform the operation should familiarize himself with the anatomy and the technic by repeated exercises on the cadaver and in the experimental laboratory. With this proviso, there is no reason why a well-trained surgeon should not perform the operation. It offers no greater technical difficulties than a cardiorrhaphy for a wounded heart or for the extraction of a bullet lodged in its chambers.

The Trendelenburg operation seems to be going through the historical evolution of all the great epochal operations. There is first the period of scepticism and doubt, then sporadic, tentative and often unsuccessful trials, and finally success and complete acceptance.

The life-saving limitations of the Trendelenburg procedure are obvious. At one time it was thought that one-half of the patients died within the first three to five minutes of the attack. More accurate observation has shown that the majority, on the basis of ten minutes' survival after the onset of the attack, could be operated upon; 20 out of 27 cases were regarded in Giertz and Crafoord's experience as operable under the most favorable hospital conditions. This, however, we must regard as a very optimistic view which may be theoretically correct but practically diffi-

cult, if not impossible to realize, even in the best hospital surroundings. The differential diagnosis at times may offer serious difficulties which justify hesitation and delay. In doubtful cases, Nystrom's suggestion to do a preliminary costochondral resection as preparatory to a later emergency operation and to do this under local anesthesia may be a helpful suggestion in the doubtful cases. However, it is significant that in 23 out of 27 cases that were under the observation of Giertz and Crafoord the clinical preoperative diagnosis was proved to be correct by either operation or autopsy. The worst prognostic feature is the possible recurrence of the embolus or the presence of multiple emboli broken up and lodged in inaccessible branches of the artery. But the 7 patients who have been saved within the last few years prove that the obstacles are not so great that many otherwise doomed patients cannot be saved and permanently restored to health and usefulness. There is no question that much judgment is required in the selection of cases. Nystrom has suggested that in patients suffering from other grave complicating diseases (cancer, tuberculosis, septicemia, etc.) and in the very aged and infirm, the operation would

probably only serve as a *coup de grace*.

The visits of Drs. Nystrom and Giertz, preceded a few weeks ago by that of Dr. Meyer, and their discussions of pulmonary embolism and its surgical treatment will no doubt help, in view of their great authority, to kindle a new interest in the Trendelenburg operation. This operation, though magnificently conceived in the fertile mind of its originator, had been followed by such discouraging results that, notwithstanding the early advocacy by Willy Meyer of New York and Matas of New Orleans, it was regarded in this country more as a matter of theoretical interest than of practical application. The recent achievements of the German and Scandinavian surgeons have brought the operation to the attention of the profession in a new light as a practical life-saving measure and have given it recognition as one of the most legitimate triumphs of modern surgery. It is hoped that the teachers in charge of the schools of operative and experimental surgery will take heed of this notable advance and make the practice of embolectomy and of the Trendelenburg operation an obligate part of the curriculum in the laboratories of operative surgery. R. MATAS.

MEDICO-LEGAL PROBLEMS*

WHENEVER someone feels inspired and impelled to launch an attack upon the administration of the law, the medical witness is quite apt to be one of his targets. The usual response of the medical profession is the charge that the situation is due to the laws, the lawyers and the judges and usually couples this with a suggestion that the laws and court procedure should be changed. While it is true that the laws and court procedure can be improved upon and that judges and lawyers could bring about a more efficient administration of the law even

without any changes being made in the laws, it is also true that the attitude of the public toward the testimony of medical experts is largely chargeable to the medical profession itself. I refer particularly to the major criticisms that expert witnesses differ so radically in their opinions and that their testimony is so often unsatisfactory and unconvincing.

Differences of opinion between expert witnesses, when analyzed, are traceable to perfectly natural causes. Where two men, though technically qualifying under the law as medical expert witnesses, differ

* An Address Delivered to the Los Angeles County Medical Association, February 20, 1930.

substantially in their qualifications of knowledge and experience, a difference of opinion may naturally be expected. Such a situation, properly handled by the court and counsel, will clearly disclose the proper weight to be given to the testimony of the respective witnesses. Improperly handled, the witnesses may appear to be equally qualified and the appearance of unjustifiable conflict of opinion thus created may be charged to causes not at all to the credit of one or both of the witnesses. In every phase of a court trial the skill of the lawyer, particularly that of the lawyer against whom an expert witness is produced, is a big factor in the weight which will be given to the testimony and this is especially true where the opposing counsel is distinctly less qualified. But a trial should not be determined by the skill of counsel. The judge should be more than a mere umpire ruling upon the objections of counsel. It should be his function to assist counsel in securing a fair presentation of the facts. He should also protect witnesses from unfair cross-examination and discourtesy of counsel and, when it appears that the counsel producing a witness has not placed his testimony fairly before the court, the court may and should ask of the witness those questions which will bring out the proof which the witness can produce. If a witness, posing as an expert, does not appear to be well qualified, it is not only proper but a true function of the court to inquire into his qualifications and the reliability and accuracy of his testimony.

As between experts of comparatively equal knowledge and experience a difference of opinion may be either honest or dishonest. It is a pleasure to say sincerely that in a trial experience of over a quarter of a century as a trial lawyer and a judge I have encountered but one medical witness who was not honest in the testimony he gave and he was thoroughly discredited at the trial. We may therefore dismiss the dishonest expert as a wholly negligible factor. Differences of opinion

between honest, qualified experts may well arise just as do honest differences of opinion between any two persons over the same set of facts. Particularly is this true in forensic medicine since it is rarely the case that the experts have at their disposal all of the material facts. Most differences of opinion between experts may be traced to a difference in the facts upon which the opinions are founded. Naturally each side of a lawsuit has a theory upon which it bases its contentions. Quite naturally the facts in the possession of the plaintiff include matters not known to the defense and information possessed by the defendant is often not known to the plaintiff. Furthermore there is a natural tendency for each party to minimize the facts which tend to support the theory of the opposite party and to lay too great a strength with the facts in his own favor. This tendency is quite prominently indicated by the statements of fact as furnished to the partisan expert. There is also a tendency to withhold from the expert those matters of information which are disputed or disbelieved. It quite naturally follows that the experts for the plaintiff receive a different statement of the facts than that which is received by the experts for the defense. Furthermore there is not always allowed to the experts for the adverse party the same freedom and latitude of examination which is afforded by the party to be examined to his own experts. To these factors must always be added the element that the experts hired by a party to diagnose his condition are more prone to believe his statements as to his condition and symptoms and the adverse experts are more likely to carry a suspicion of possible malingering. These elements and some others of more occasional character are inherent in the system of trial where each party provides his own experts. As suggesting a remedy or improvement let us consider for a moment as a concrete topic the insanity defense in a criminal prosecution.

Before the amendments to the California statutes relating to the defense of insanity, it was the usual thing for each side to have its own experts; the prosecution produced experts who were of the opinion that the accused was sane while those produced for the defense were of the contrary opinion. I have a suspicion that in some cases one of the parties failed to call as a witness an expert who, though originally employed, did not hold an opinion consistent with the theory of the party who sought his services. Under this form of procedure the facilities afforded the prosecution alienists were ordinarily not the same as those afforded the doctors for the defense. It was not at all an unusual occurrence to find defense counsel insisting on being present when the prosecution alienists examined his client, frequently, when present, interfering with and preventing a proper examination. In one instance an attorney for a defendant absolutely refused to permit an examination of his client by the doctors for the prosecution and did not consent to such an examination until after the trial had actually commenced and then only when informed by the prosecutor that, if he persisted in his refusal, the fact that he had prevented such an examination would be proved at the trial. Another factor which cannot be ignored when experts are employed by the respective parties is the influence, conscious or subconscious, which is likely to result whenever an expert is employed, especially when his employment comes from a lawyer of high standing in his profession and in whose honesty and sincerity the physician has full confidence. Quite naturally under the old system of procedure the trial, so far as the issue of insanity was concerned, became a contest of experts and lawyers and, in the heat of that contest it was to be expected that the experts would develop not only a tendency to become partisans but at times even became champions for their respective sides of the question. After all it is rather human to enjoy a good scrap.

Under the present law of California, where the court, immediately upon the entering of a plea of "not guilty by reason of insanity," appoints a committee of experts to investigate and inquire into the merits of the defense of insanity and to render a report to the court of their findings, it has been the experience that the experts appointed substantially agree in their conclusions and, where differences of opinion exist, they are reasonable differences of opinion, due to the manner in which the symptoms, history and other factors were viewed. While the present law has been in operation only since August 1929, it has been invoked with sufficient frequency to justify the belief that it will operate as well in the future as it has in the past and its success and practicability are chiefly due to the following factors: First, the experts are not selected by, or in any sense bound to or compensated by, either the prosecution or the defense. Second, the court in making its appointments is entirely free from any partisan desires in the selection of the experts but selects its commission from among those members of the medical profession whom it deems well qualified. Third, and perhaps most important, the experts are each given a full and equal opportunity of learning all about the case unhampered by the interference of counsel. Of especial importance to the medical profession is the fact that, since the experts are appointed by the court and hence are non-partisan, their testimony is more nearly accorded the weight to which it is entitled, for the jurors look upon the experts appointed by the court as somewhat in the nature of officers of the court and, as such, entirely free from any partisanship or interest in the ultimate outcome of the case. Under this new order of things also, the attitude of the attorneys has undergone a distinct change. Cross-examination has become more of an inquiry to elicit information in addition to that which was brought out on direct examination, rather than, as was the former usual practice, an attack directed against

the witness. Trial lawyers of ability are fully aware of the prejudicial effect of any effort on their part to attack or discredit an expert witness appointed by the court, virtually vouched for by the court. While both the prosecution and the defense retain their former right to bring in experts of their own choosing, in addition to those appointed by the court, it is apparent from the past experience that this production of partisan experts is most unlikely to occur. If partisan experts should be called in and a conflict in testimony should arise between them and the experts appointed by the court, all natural tendencies would cause the jurors to give greater weight to the testimony of the court appointed experts. It is believed by those who have closely followed the operation of the new laws relating to the insanity defense that they come closer to producing a just verdict or decision than was possible under the former procedure. A method of procedure which works so well in cases involving questions of psychiatry is certainly worth trying in all cases involving expert testimony. Even under the new law relating to the defense of insanity there is much room for improvement, particularly in the provisions relating to the selection of experts by the court. That provision which arbitrarily requires that at least one of the experts appointed must be connected with one of the state hospitals is particularly impractical in those counties far removed from any one of the state hospitals and it is always unwise to interfere with the full exercise of the discretion of a court, particularly in the matter of the designation of experts in whom the court has personal confidence. The law is also somewhat ill advised in that it requires the commission of experts to consist of two or three members. While the courts no doubt have the power to nominate more than three experts, it is mandatory that at least two be appointed. It is well known that there are cases in which the insanity of the defendant is so obvious that no

good reason can exist for the cumbersome and more expensive method which requires more than one expert.

Much as we may deplore it, the fact remains that the general public has a lack of confidence in medical testimony and that this sentiment exists in the minds of many jurors and, to an extent at least, in the minds of the judges. The fact that this impression is largely unwarranted does not alter the unfortunate situation. But, since it does exist, it must be met; as far as it is unwarranted it must be overcome, and, insofar as it is justified, an effort should be made to remove the cause. Until this is done, every medical expert called as a witness must not only give his testimony but must also overcome any prejudice which may exist in the minds of those members of the general public who have to pass upon his testimony. This handicap of prejudice is due in no small part to the errors of commission or omission of the expert medical witnesses who have gone before him and is not an inherent characteristic. In foreign countries medical testimony is given far greater consideration than it is in this country and the expert is looked upon by the court and jury as a man whose testimony will bring to their assistance the full benefits of modern scientific knowledge.

While the gaining of the confidence of the court and jury depends in no small measure upon the personality of the witness, his conduct and appearance upon the witness stand; the weight which will ultimately be given to his testimony depends most largely upon the impression which the testimony itself will create. The giving of expert testimony in court is an art which is not inherited but must be acquired. No physician can say with any assurance that he will not be called into court during the coming year to render some medico-legal service and still, unless he be one of the rare few who, by study or consideration or actual experience or their combination, have learned the art of giving expert testimony,

the chances are that, if he is called, he will not only fail to do himself justice but will not render that degree and quality of service which modern medical science can bring to the assistance of the court. While this must naturally follow where the doctor is not possessed of a sufficiently thorough and accurate knowledge of the subject involved, a similar result follows where, even though the physician possesses the necessary skill and knowledge of the medical question involved, he lacks a knowledge of the manner of solving the question referred to him both as to the manner of conducting his investigation and as to the manner of testifying after he arrives in the courtroom.

The skillful trial lawyer is always mindful of the fact that a jury is composed of average citizens of the community to whom the matters and subjects involved in the trial are largely new and novel. Consequently he directs his efforts not only to the end of proving the facts making up his case but to proving them in so clear and conclusive a manner that every juror not only understands every word of the testimony but is convinced thereby. More than half of the verdicts of juries which have been criticised as being an unjust determination of the issues involved are more properly chargeable to the manner in which the lawyers and witnesses performed their functions in the courtroom. Both the witnesses and counsel must constantly take into consideration that the jurors are just average citizens, that their duties as jurors are most likely different from any experience they have had theretofore, that many of the facts in the case involve matters of knowledge which are entirely new to at least a portion of the jury and that the witness is rather an educator than merely an individual stating ultimate facts. It is not at all unusual, when discussing with a juror the facts of some case in which he served, to find that he had arrived at a conclusion on the facts not warranted by the testimony as that testimony would

be analysed by a trained and experienced judge or lawyer. A careful examination and review of the testimony will usually disclose that the real fault lay, not with the juror, but with the manner in which the proof was introduced. The average witness is so familiar with the subject matter of his testimony that he wholly overlooks that he is relating something which is wholly new to his hearers and fails to pay any consideration to the fact that the very purpose of his being on the witness stand is to transfer his knowledge to the minds of the jury. Thus a physician and surgeon who has examined the person of a litigant for the purpose of testifying to his physical condition is quite likely to come into court and testify to his findings in much the same manner that he would report the case to a group of doctors. To aggravate the situation the lawyers, desiring to display their knowledge of medical science (quite often acquired by a brief period of reading of an obsolete textbook) conduct the examination of the doctor in much the same tune, with the results that the jury, unable to grasp what it is all about, directs its attention elsewhere and to something more interesting. This is due in part to the perfectly natural use of scientific terms by the expert. While not a part, except indirectly, of my topic, I should like to repeat what was said on a former occasion that every witness, be he expert or layman, should give his testimony in such language that it will be fully understood by every member of the jury. This must be particularly difficult for the expert witness for, in spite of all that has been said on the question, our experts still testify far over the heads of the jury. Where the proceeding is a trial or hearing before a judge without a jury it may be a delicate compliment to the court to use as technical language as possible, but the decision will be most likely to go to that side whose understandable testimony is most convincing. The ability to testify in non-technical language is and can only result from a

clear grasp and understanding of the subject coupled with careful thought and consideration before taking the witness stand. The expert must develop an ability analagous to that of the successful teacher or instructor.

The point, however, to which I desire to call particular attention here is that of the preparation of the subject matter of the testimony to be given. The expert must always bear in mind that the objective is not that he convince himself as to the ultimate fact or facts but that his efforts must be extended far beyond that point and must be directed to the production of proof so that the final judgment of the court in which the trial is had, shall be in accord with the facts, a result which can only be attained if the judge, or the jury if it be a jury trial, receives all of the proof necessary to such a determination. No judge or jury will accept the opinion of an expert witness merely because he declares it from the witness stand. The opinion should always be supported by the facts upon which that opinion is based. It must be anticipated that, before the expert leaves the witness stand, he will be called upon to give the reasons and basis for his opinion. It would surprise the medical profession if they knew how many of their brother physicians have failed to convince the court or jury because of the incomplete or unsatisfactory basis of their expressed opinions. Take a case in which the doctor has testified that, in his opinion, a defendant is suffering from a particular disease. When called upon to state the basis of his opinion it develops that his opinion is absolutely dependent upon the statements of the person examined and that the doctor's conclusion can, therefore, be correct only if the statements of the patient were true. This reduces the decision of the question of fact largely to the truthfulness of the patient's declarations to the doctor and, the defendant being a very much interested party to the action, it is but natural that the weight given the doctor's opinion is

ultimately determined by the credibility of the patient. This type of case occurs quite frequently. Not so long ago I received an opinion from a physician that a defendant who had been convicted of shoplifting, after about ten years of activity in that line of business, was suffering from kleptomania, his opinion being based entirely on the statements of the defendant that she didn't know why she had stolen things and had only stolen articles of small value. This same defendant had made statements after her arrest and had testified at her trial entirely at variance with her statements to the doctor; in other words his opinion was based on only part of the available information. I am satisfied that, had he heard the woman's testimony on the witness stand, he never would have formed the opinion that she was a kleptomaniac. In his private practice the physician is warranted in believing the statements made to him by the patients who come to him for relief. They are not viewed as possible malingerers but are credited with sincerity even though it should ultimately develop that their ills are largely or wholly imaginary. But, when the patient is a party to a lawsuit or criminal prosecution, every effort should be made to guard against being imposed upon by a statement of facts and symptoms which have no basis in fact. Some years ago one of our well-known psychiatrists was appointed by the court to examine a prisoner in jail and later took the stand and testified that, in his opinion the prisoner was insane. Shortly thereafter the same prisoner came into court and pleaded guilty to two robberies, admitted that he had not had any of the symptoms upon which the doctor had based his opinion and that, so far as the objective symptoms were concerned, they had been feigned and then laughed over the way he had fooled one of the doctors. I must admit that this prisoner was one of the most clever malingerers I have ever met and his simulation of insanity was nearly perfect. The fraud was exposed only by

going beyond the prisoner's own statements and appearance at the time of the examination. The interested party in pending litigation may be an out-and-out faker or merely an unconscious malingerer; but such possibilities always exist and must be guarded against. The legal profession is well aware of the fact that the client who will give a fair, accurate and unbiased statement of the facts is an extremely rare individual. It seems almost inevitable that a client, like a young man courting a girl, will put forth in somewhat magnified form everything in his favor and entirely overlook or at least minimize everything to the contrary. This desire to exaggerate is well illustrated by a recent occurrence in a case in which a defendant desired to be released on bail pending an appeal after conviction of a felony. To support his claim that confinement in jail was imminently dangerous to his life, affidavits of physicians were filed in one of which appeared the statement that every meal taken by the prisoner after his commitment to jail several months previous had been forced. The testimony taken upon the hearing showed that there had not been a single instance of forced feeding. In the same set of affidavits it appeared that the statements as to the prisoner's weight as given by him were changed after the affidavits had been signed because it was discovered before the affidavits were filed that such statements of weight were not correct. To an ordinary person it would appear that the accurate way to get a man's weight is to weigh him and not accept his statement where weight is a factor in a diagnosis. What has been suggested in relation to the statements of the interested party himself applies largely to statements of friends and relatives. It is surprising how many conclusively insane acts of a defendant are discovered after he has murdered someone. Statements as to family history and past history of the patient, even in private practice, are very likely to be inaccurate or unreliable. People really know very

little about the cause of death of an ancestor or relative; what information they may once have had may be forgotten or, if not forgotten, may originally have been erroneous. This latter situation is quite likely to exist where the actual cause of death or a contributing cause of death is one of those diseases which people prefer not to mention. In addition to these possible defects in the statements of friends and relatives of a party to litigation the doctor must also guard against direct falsehood uttered to assist the litigant. One would hardly expect that the ordinary person charged with a crime could possibly feign insanity and still we have had instances right here in Los Angeles of prisoners who have so successfully feigned the symptoms and appearance of the insane as to fool able psychiatrists. In making this statement I have no reference to those cases in which the only proof of the absence of insanity is the verdict of a jury, but have in mind those cases in which the fact of malingering was conclusively established. If a man of the criminal type can so effectively simulate insanity with its complexity of symptoms, the possibility of a party to a lawsuit feigning a simpler ailment is apparent. The medical expert owes it not only to the courts and the interests of justice to use every possible precaution against deception but is obligated to the members of his own profession to do so lest, should he be deceived into giving an opinion not warranted by the actual facts, he cast discredit upon expert medical testimony in general. The attitude of the public toward the medical expert which now exists is based upon what it has heard and observed of the conduct and testimony of medical experts in the past. This attitude is largely unjustified, especially in so far as it is based upon the facts that experts have given diametrically opposed opinions and, in so far as it is justified it should be limited to those members of the profession who are no credit to it. The remarks in this discussion are largely directed in an effort to point out a means

of eliminating much of this adverse criticism in the future. Every time a physician and surgeon renders medico-legal service it should be of so high a character that it will be a credit to medical science. This means careful study, research and preparation, and a high sense of loyalty and devotion to his profession.

One of the minor contacts between the doctor and the court arises when a patient requests his physician to provide him with a very necessary certificate of disability to explain or excuse his attendance in court, the patient usually expecting a certificate containing as much evidence of trauma or pathology as possible. Having seen a goodly number of certificates of this character I am firmly convinced that the medical profession is not only extremely ignorant of the legal requirements but also rarely, if ever, considers the impression which the certificate will leave with the judge to whom it is ultimately presented. We are all aware and appreciative of the psychological effect of a well written letter on good stationery and, if we gave the matter a moment's thought, we should realize the effect of a hastily scrawled certificate written on a prescription blank. To make matters even worse the actual information which such a certificate should contain, the facts about the patient, are often conspicuous by their absence and the certificate consists usually of no more than an expression of the doctor's opinion as to how long the patient will be incapacitated. Add to all this the chances that the doctor is not known to the judge and it doesn't require higher mathematics to figure out the weight which the certificate will carry. Again, it not infrequently occurs that the certificate unjustifiably represents a condition which does not in fact exist. This is not due to any desire on the part of the physician to mislead the court but because he too carelessly accepts the statements of the patient and predicates his certificate upon those statements. In other instances a physician is called in

for virtually the sole purpose of securing a medical certificate from him. Not so long ago a defendant in a criminal case failed to appear in court when required and his attorney presented a medical certificate which his client had sent him. The certificate stated that the patient was suffering from nephritis and prostatitis, was confined to his bed and could not possibly be in court for at least several weeks. The district attorney knew the defendant better than did the doctor and sent two police officers to the defendant's residence to check up on him. They found the defendant up and about without any signs of any disability and on his desk found a letter to a pal, just completed, telling him how he had fooled a doctor into giving him a medical certificate and thereby evaded going to court. The defendant was taken to jail on a bench warrant and, though thereafter kept in jail to insure his presence when required, displayed no marked symptoms of any incapacity. An examination of the physician disclosed the fact that he had seen the patient on but one occasion and that his certificate had been based on what the patient had told him. It does not require many such experiences before a judge looks upon a medical certificate with considerable suspicion unless he happens to know the physician. The only safe course is never to certify to anything that would not be stated in the same manner under oath. Every such certificate should give an accurate picture of the case, stated in plain language, and, when the certificate contains a statement of the probable duration of the incapacity, the reasons for such opinion should be stated. This will entail special effort but then the impression created by a certificate is normally proportionate to the effort displayed. It must be borne in mind in this connection that proof in any court proceeding must be under oath and that the acceptance of an unverified certificate is a matter of courtesy on the part of the court.

In all matters of any particular importance the medical certificate should be in the form of an affidavit and sworn to before a notary or other officer authorized to administer oaths. The affidavit should contain a statement of the doctor's special qualifications as that will largely determine the weight which will be given to his statements and should conform to the suggestions elsewhere made in connection with the subject of oral testimony. It is the common practice for the lawyer to draft the affidavit for the doctor, but if this be done, it should be carefully edited by the affiant. The better practice would be for the doctor to personally prepare the body of the affidavit.

There is one class of cases in which the doctor is called upon to treat or examine a patient or to conduct a post-mortem examination and which eventually become the subject of a trial in court. While the probabilities of the resulting trial can usually be anticipated from the nature of the case it is the rule rather than the exception that the doctor makes no special preparation for his eventual appearance in court. When he does arrive in court we frequently find that his memory is extremely hazy as to the conditions and facts of the case and that his personal records are so incomplete that they are useless as a memory refresher. The law makes it a misdemeanor for any physician and surgeon to fail to immediately report to the local police or to the sheriff if the case be outside municipal boundaries, every case handled by him in which the patient is suffering from an injury caused by a deadly weapon or by a violation of any penal law of this state. This report must state the nature and character of the injuries but, in spite of the obvious wisdom of the requirement, we find only a limited compliance with its provisions, the average report being most meager in its statements of fact. Even independent of the law the minor as well as the major injuries should be carefully noted, not because of their

medical but because of their medico-legal and evidentiary value. A few minor scratches on the forehead of a man arrested for driving an automobile while under the influence of intoxicating liquor may be of no interest to the police surgeon who is giving him a test for sobriety; but when the doctor arrives in court he is apt to find himself being asked whether he noticed the injuries to the defendant's head and usually his testimony is that he is unable to state whether any such injuries were present. By the time the trial ends we find the defendant contending that his unsteady condition was due to head injuries received in the collision, a contention which the doctor would have been able to disprove or verify had he performed his full duty. As a police surgeon he should have anticipated that very common line of defense and be prepared to give all the ascertainable facts when called for, not only because of their evidentiary value, but because the admission that he does not know whether the defendant had any head injuries tends to show that his examination was not thorough and his evidence is consequently discounted. In a case of the character last referred to and recently tried, the police surgeon testified that he had no knowledge that the defendant had suffered any injuries when the fact was that he had suffered a fracture of several ribs. In examinations for sobriety the element of thickness of speech is a distinct factor and the defendant quite often endeavors to account for the thickness of speech by claiming that his speech is normally thick and indistinct, that his nationality gives him such type of speech, that he was dazed by the accident or that he had a new set of false teeth. I am still awaiting the testimony of a physician in such a case, differentiating the speech of an alcoholic from defects of speech from other causes.

The location, direction, size and appearance of wounds are of distinct importance in the prosecution of the assailant,

but the private practitioner usually has only the most indefinite recollection as to these matters. Recently a doctor testified in one of our courts to treating a boy who had been shot through the abdomen but was unable to tell whether the wound was on the right or the left side. Naturally juries will discount the testimony of a doctor who is unable to give the information which he should be able to furnish if his examination were thorough, especially as to so obvious and important a fact as the location of the bullet wound. Even in cases of post-mortem examination we find at times a lack of scientific precision. An autoptical examination such as would be made by a first-year medical student is not up to the standard expected of a graduate physician. Some years ago two of our local doctors were present and participated in the post-mortem examination of a man who had been shot to death. During the trial for homicide which followed it became important, as tending to prove the positions of the deceased and the accused at the time the shot was fired, to prove the exact location of the entrance and exit wounds. Both doctors testified positively as to the exact location of the bullet holes, but one of them placed the exit wound six inches higher up on the back than did the other. The district attorney had to exhume the body to settle the question. In another case the lip of the deceased was found cut entirely through. The nature of the instrument causing this particular injury was very important but the autopsy surgeon was unable to express an opinion as to whether the wound had been caused by the sharp edge of a knife or by a blunt instrument like the butt of the handle of a butcher knife. In still another case the autopsy surgeon testified that he had performed an autopsy and that death was due to a gunshot wound of the chest passing through the heart but admitted on further questioning that he did not know what part of the heart the bullet had passed

through. Instances of this kind of testimony, and others might be cited, are and have been an important factor in the formation of the regard in which the public holds the medical expert witness.

Much of the cause for the failure of the doctor to be able to give all the details which a thorough examination would have disclosed is the fact that he stopped as soon as he had performed his functions as a physician or had ascertained the cause of death and overlooked his function as a medico-legal expert. Whenever a physician has any reason to believe that he may later be called into court as a witness, his examination and observations should be conducted with scientific accuracy not only as to the principal subject of his attention as a physician, the condition requiring medical or surgical attention, but to every physical sign which could by any possibility be of evidentiary value even though it be a mere scratch. And, since human memory is fallible, these facts should be carefully and fully recorded in a notebook, supplementing the written word by a diagram whenever possible. Such a record is not only valuable for the purpose of brushing up the memory before going into court but the law permits the doctor to consult such a memorandum while on the witness stand for the purpose of refreshing his memory.

When a physician is called in as a medico-legal examiner to examine an individual for the purpose of establishing a fact by the application of the resources of medical science, he should bring to bear upon the problem the highest degree of skill, knowledge and accuracy of detail of which he is capable. This one subdivision of our subject is itself so extensive as to merit a lengthy presentation and citation of illustrations, but this occasion permits of but a single illustration. Let us consider a charge of rape. While there are not many cases of rape accomplished by means of force or fear, most states punish what is known as statutory rape in which the lack of consent of the female is not an

element of the crime, the offense consisting in the commission of the sexual act with a female under a certain age, eighteen in California. In either class of case one of the important facts to be proved is that an act of sexual intercourse took place and in nearly every case the prosecutrix is turned over to a physician for examination for the purpose of obtaining medical testimony on this issue. If an experience of about ten years in the office of district attorney supplemented by about two and a half years as judge presiding over criminal trials were my sole source of information, I would be forced to conclude that all that medical science can do towards determining whether a female has had an act of sexual intercourse, unless pregnancy or venereal disease is present, is to determine whether the hymen has been ruptured and whether the rupture is recent. Even here the doctor must admit that a ruptured hymen may result from causes other than sexual intercourse. During this twelve or more years of experience there were only two cases in which spots on the clothing were examined to determine whether spermatozoa were present; but even a positive finding from such an examination would prove only that there had been an emission and would not prove a penetration of the female sexual organs. It would seem logical that, since in completed sexual intercourse millions of spermatozoa are introduced into the vaginal tract, medical science could discover the presence of a few of them if an examination were made within a reasonable time after the sexual act and that their absence upon an examination shortly after an alleged act would have the tendency of rather conclusively proving that such an act had not taken place provided that the absence of spermatozoa was not accounted for by some additional factor. The answer as to why such examinations are not made would be interesting. So also would be an explanation of the testimony of three doctors in a recent case. Each testified

to having examined the prosecutrix; one testified to finding the hymen ruptured, a second that the hymen had not been ruptured and the third testified that he could not determine whether the hymen had been ruptured or not.

Whenever a doctor starts out to discuss the subject of expert medical testimony we may confidently expect that before he concludes he will have criticised court procedure and the rules of evidence. Some of this criticism may be justified but most of it is due to a lack of knowledge or misunderstanding of the law. Criticism of the law by a doctor who is not familiar with its provision may satisfy his personal feelings but gets us nowhere. It is interesting to note that most of the criticism comes from the doctor whose knowledge of the law is based almost entirely upon personal experience in the courtroom. It is undoubtedly often true that the expert medical witness leaves the witness stand with a feeling that he was not permitted to give the testimony he had expected to give. This may have been due to the fact that he did not know how to testify but is more likely attributable to the fact that the lawyer who called him as a witness did not know how to bring out his testimony. The percentage of lawyers who do not know how to put on expert medical testimony is fully as high as that of the doctors who do not know how to testify. Dr. Edward Huntington Williams has given us an excellent contribution on this subject in his recent book, "The Doctor in Court." Dr. Paul E. Bowers, also a member of your association and one who has studied law, at a joint meeting of the Los Angeles Bar Association and the Los Angeles County Medical Association in November 1928, also discussed the expert witness in an able but all too brief address which was later published,¹ and, in concluding, suggested that the two learned professions make a real effort to cooperate in a solution of the problem. Without a mutual understanding of the

¹ *Inter. Clin.*, s. 39, vol. 3.

respective viewpoints of the two professions of law and medicine the problems cannot be solved, for many of the problems are the direct results of misunderstandings. Meetings attended by members of both professions at which the subject is discussed will do much toward improving conditions, but the discussions must be frank as well as friendly even though at times the frankness may not be alto-

gether pleasant. Above all there must be an individual willingness and desire to study the problems and an individual effort on the part of every doctor to make the medico-legal expert just what the term implies.

CHARLES W. FRICKE, J.D., LL.M.
Judge of the Superior
Court of Los Angeles
County, Calif.

FLUOROSCOPIC CONTROL OF FRACTURE SURGERY

DURING the last decade surgeons have developed a commendable increase in interest in the radiosopic control of their traumatic work, especially during the actual setting of fractures. In a few large hospitals where there is much of this work to be done, the x-ray department has been equipped with a special room and a special table for this type of fluoroscopy permitting simultaneous observation in two planes, always depending upon trained medical personnel from the x-ray department to do the fluoroscopic work. The example set in these large, well-equipped hospitals has been contagious, and very naturally there has resulted a commendable desire on the part of surgeons generally to utilize the fluoroscopic control in their fracture work. Unfortunately, the majority of hospitals, especially the smaller ones, do not have the full-time services of a physician radiologist, so that many surgeons either by choice or by force of circumstances have come to do their own fluoroscopic observations, usually with a radiological technician turning the current on and off at the command of the observer.

The advance in traumatic surgery represented by this screen control of the setting of the fractures is not without its dangers, however, especially in those cases where the surgeon prefers or is obliged to do his own fluoroscopic observations. Radiological technicians are not, and by the very

nature of things cannot be, expert in radioscopy. They are not physicians and at no time in their work or training do they have opportunity or need of equipping themselves to do fluoroscopy. Hence, all that the technician can do in connection with fluoroscopy of fractures is to start and stop the current at the behest of the surgeon. Very few physicians not specializing in radiology have any definite idea of how much x-radiation can be safely administered at one sitting; indeed, few have any definite conception of how much radiation is being received by the part per minute. The chief advantage of the foot-switch, with simultaneous control of x-ray and overhead light, as introduced by the writer into fluoroscopic work in 1908, lies in one's ability to keep the current off at all moments the eyes are not intently fixed on the screen and ready of immediate observation. The current should never be on one single second uselessly, that is, when the observer is not alert and ready to look. This means that the observer will make no attempt to fluoroscope the patient until he has been in darkness or very obscure light for at least fifteen minutes; for any attempt to use the screen sooner will require a much higher milliamperage than is necessary or safe. With a foot-switch of this sort adequately used the actual dose of x-rays received by the patient may be reduced threefold or fourfold. A sheet of aluminum of 1 mm. thick-

ness should be fixed in place between the tube and the patient for all screen work. In fact, it is best to leave it in place for all kinds of diagnostic work, whether by film or by screen.

The writer has been surprised at the apparent carelessness with which he has seen the occasional radiologist subject

patients to prolonged fluoroscopic observation in connection with fracture or foreign body surgery. Many medico-legal cases involving the use of the x-rays have resulted from such unwise prolongation of the screen control. This word of warning should not be amiss.

JAMES T. CASE.

FOR POSTERITY

THE portraits of men of achievement in any of the high professions should be painted by the worthy portrait painters of their country during their lifetime. While record of the actual work of our great men is carefully made and preserved the equally important contribution to history and posterity in the shape of a good portrait is more than often omitted. It is only when the famous doctor or engineer or philosopher or artist has passed on, that a regretful family seeks out a painter, presents him in most instances with a poor retouched photograph and begs for a lasting memorial of the departed husband, son or father who has labored faithfully for the advancement of his craft and the benefit of his community.

That photography has made tremendous strides in its artistic evolution no one will deny. Lighting, composition, fine printing are in many instances amazingly excellent, yet it is well to remember that after these attributes of a good photograph have been duly considered and accomplished, the mechanical click of the instantaneous shutter tells the final story.

The genius, the selective and observing brains of the well-equipped portrait painter are action of another and far more valuable

caliber in setting down the essence, in the subtle personality, the speaking quality, to use a trite but none the less expressive term, of a man.

How valuable too, to the institutions where these men of achievement have worked, is a collection of their portraits; how much better than all the biographies does a good painting portray them and help not only as fitting adornment for the walls of their workshops, but as an inspiration to their younger successors in carrying bravely on!

The two group portraits of Dr. Gross and Dr. Agnew in their respective clinics painted by the great Thomas Eakins of Philadelphia are interesting. Sargent's splendid group of Drs. Osler, Welch and Kelly of Johns Hopkins also comes to mind as does the recently painted group of doctors, ex-internes of the Lankenau Hospital, Philadelphia, surrounding Dr. John B. Deaver in his operating room, painted by Albert Sterner.

What finer gesture can be made by a college, medical society, hospital group or group of public spirited citizens than to have done, in oils by worthy painters, portraits of their physicians who have achieved unusual distinction! T. S. W.

ABORTION AND CONTRACEPTION

To the Editor:

In response to your invitation to comment on the editorial by Dr. Gordon in your March issue, in which the doctor unhesitatingly condemns abortion and contraception, I wish to take issue with his stand. In Ohio we have a statute in accordance with which if three physicians concur in a decision that abortion is necessary to save the life of the mother, the production of such an abortion is legal. Many abortions have been induced in this state in accordance with that statute, and I think the statute has the approval of practically all our physicians.

When Dr. J. Whitridge Williams published the paper to which Dr. Gordon refers, I heartily approved of his attitude and promptly wrote him a note of congratulation over his frank and sensible attitude, and I have seen no adverse comment except this editorial by Dr. Gordon.

On general principles, to which, however, there may well be exceptions, as in some of the cases reported by Dr. Williams, abortions should be done only to save the life of the mother, or at least to save that life from extreme jeopardy. When it comes to contraception, however, conditions are different, and the judgment of the physician has a much wider range. I firmly believe in contraception in cases of mental and physical diseases which would probably be transmitted to the offspring, or in which pregnancy would be apt to affect deleteriously the life or health of the mother. There are many

other conditions which demand humane and intelligent consideration, and the decision as to advising contraception can be reached only after the exercise of well-balanced judgment.

I feel that every woman has certain personal rights in the matter of maternity, and I have never had any sympathy with surgeons who refuse to side-step the tubes to prevent future pregnancies in cases of cesarean section. I have made many such sections, but invariably I ask the woman and her husband as to their desires for more children by the same method, and if they express a wish that there shall be no more pregnancies I always side-step the tubes. In only two instances has the mother expressed herself against it: one of them had the tubes side-stepped after the second cesarean section, but the other still persisted in their preservation at the second section, but years have gone by and she has had no further pregnancies and is now well past that possibility.

There is one church which we are told absolutely forbids any interference with the life of the fetus, or in any procedure that shall prevent pregnancy; and I can easily understand how a physician brought up in the tenets of that church might oppose both procedures, but aside from that I see no reason why the wishes of the husband and wife should not be paramount. If any of my patients in whom I have thus side-stepped the tubes have regretted it, I have not heard of it.

J. F. BALDWIN, M.D.
Columbus, Ohio.

FOUR INDEX NUMBERS A YEAR

This number marks the completion of the first volume of THE AMERICAN JOURNAL OF SURGERY since the increase in size in January, 1930. It comes to 1370 pages. As this makes a volume of unwieldy proportions, we will, beginning with July,

1930 (Volume IX), publish four volumes a year, instead of two, issuing indices with the September, December, March and June numbers. Consultation with librarians and subscribers has shown that this is a more desirable and practical method than to

attempt to continue only two volumes a year. It is found that an increasing number of subscribers are keeping bound files of THE AMERICAN JOURNAL OF SURGERY.

These present a record of the surgical progress of the day, and the extra indices are published in the interest of our subscribers.

THE AMERICAN ASSOCIATION FOR THE STUDY OF GOITER

ANNUAL MEETING 1930

JULY 10 AND 11, SEATTLE, WASH.

JULY 12, TACOMA, WASH., AND MOUNT RAINIER

Thursday, July 10

- 8:00—Registration, etc., at the Olympic Hotel
- 9:30—Address of Welcome. HON FRANK E. EDWARDS, Mayor of Seattle
- 10:00—President's Address. DR. E. R. ARN, Dayton, Ohio: Auricular Fibrillation Associated with Hyperthyroidism
- 10:30—JOHN MARTIN ASKEY, Los Angeles: Blood Pressure and Goiter, a Preoperative and Postoperative Study
- 10:45—E. P. SLOAN, Bloomington, Illinois: Anatomy of the Thyroid Region
- 11:00—WM. ENGELBACH, Santa Barbara, Calif.: Simpler Diagnostic Methods of Endocrine Disorders
- 11:15—W. O. THOMPSON, Chicago: Course of Exophthalmic Goiter Following Subtotal Thyroidectomy
- 11:30—LEROY LONG, Oklahoma City: Some Remarks on the Management of Hyperthyroidism
- 11:45—RAYMOND J. MILLZNER, Oakland, Calif.: Parathyroid Studies
- 1:00—LEO P. BELL, Woodland, Calif.: Tumors of the Neck Simulating Goiter
- 1:15—C. A. ROEDER, Omaha, Neb.: The Third Type of Toxic Thyroidism
- 1:30—MARTIN B. TINKER, Ithaca, N. Y.: Thyroiditis
- 1:45—J. RUDOLPH E. SIEVERS, Butte, Mont.: Influences Bearing Upon End Results in Goiter Treatment
- 2:00—E. P. McCULLAGH, Cleveland: Relationship of Carbohydrates to Calcium and Phosphorus Metabolism in Tetany
- 2:15—GORDON S. FAHRNI, Winnipeg, Canada: Effects of Thyroidectomy Upon Pregnancy
- 2:30—WILLIAM J. KERR, San Francisco: Necrosis of the Heart and Liver in Thyrotoxicosis
- 2:45—GENERAL DISCUSSION
- 4:00—RALPH R. WILSON, Kansas City, Mo.: Effects of Thyroid Activity Upon the Female Organism
- 4:15—JOHN S. HELMS, Tampa, Fla.: The Incidence of Goiter in the Southeastern States and Its Possible Significance
- 4:30—H. W. RIGGS, Vancouver, B. C.: Adenomatous Goiter
- 4:45—GENERAL DISCUSSION
- 7:00—Boat Ride

Friday, July 11

8:00 to 10:00—Surgical Clinics. Doctors BRIEN T.

KING, A. J. BOWLES, C. C. TIFFIN, J. TATE MASON, and J. C. MOORE.

- 11:00 to 12:00—HENRY S. PLUMMER, Rochester, Minn.: Thyroid Therapy
- 1:00—S. D. VAN METER, Denver: Classification of Goiter
- 1:15—THOMAS M. JOYCE, Portland, Ore.: Preparation of Thyroid Patients for Surgery
- 1:30—LEWIS M. HURXTHAL, Boston: Cardiovascular System in Goiter
- 1:45—NORRIS W. GILLETTE, Toledo, Ohio: Complications Following Thyroidectomy
- 2:00—THOS. O. BURGER, San Diego, Calif.: Local Anesthesia with Adjuncts for Thyroidectomy
- 2:15—ALLEN GRAHAM, Cleveland: Malignant Tumors of the Thyroid, a Study of End Results
- 2:30—WILLARD BARTLETT, JR., Saint Louis: Additional Method of Determining the Operative Risk in Goiter
- 2:45—J. EARLE ELSE, Portland, Ore.: Prevention of Postoperative Recurrences in Thyroidectomy
- 3:00—JOSEPH L. DECOURCY, Cincinnati: Rare Tumors of the Thyroid Gland
- 3:15—GENERAL DISCUSSION, Opened by WM. O. SWEET, Phoenix, Ariz.
- 3:45—ROBERTSON WARD, JESSIE L. CARR, San Francisco: Malignant Goiter
- 4:00—ADDISON G. BRENNER, Charlotte, N. C.: Hyperthyroidism and Hypothyroidism Following 2500 Thyroidectomies
- 4:15—LINDON SEED, Chicago: Differential Diagnosis of Thyrotoxicosis and Neurosis
- 4:30—GENERAL DISCUSSION
- 7:30—BANQUET. Address by KARL F. MEYER, San Francisco.

Saturday, July 12

- 8:00 to 9:00—Diagnostic Clinic: ARNOLD S. JACKSON, Madison, Wis.
- 9:00—EARLE DRENNEN, Birmingham, Ala.: Analysis of 125 Operations on the Thyroid Gland
- 9:15—O. P. KIMBALL, Cleveland: Relation of Endemic Goiter to Mental Deficiency
- 9:30—WARREN H. COLE, Saint Louis: Experimental Production of Pathological Changes in the Thyroid by Infective and Chemical Means
- 9:45—HENRY J. VANDENBERG, Grand Rapids, Mich.: How Long Is a Toxic Goiter Toxic?
- 1:00—Luncheon at Tacoma, with Pierce County Medical Society. E. STARR JUDD, Rochester, Minn.: Treatment of Peptic Ulcer and Gallbladder Disease Complicated by Hyperthyroidism T. ADDIS, San Francisco: Do Cases of Bright's Disease Have Disturbances of the Thyroid Gland? Dinner at Paradise Inn, Mount Rainier.

“ADDISON’S DISEASE”

A COLLEAGUE of Richard Bright at Guy’s, known as an inspired pathologic lecturer and diagnostician rather than as a successful practitioner, Thomas Addison was born near Newcastle in 1793. He graduated in medicine at Edinburgh in 1815, after which he settled in London.

We are told his manner was repellent and haughty. However, this aloofness was a defensive mechanism to hide a shy and excessively sensitive inner-man. Because of these characteristics he never had a large practice. Perhaps it is well that this was the case. To his students and his hospital he gave unstintingly of the best that was in him.

He was decades ahead of his time in that he had little use for the polypharmacy of those days. It is said that he often left his patients forgetting to prescribe for them. However, “Addison’s pill,” composed of calomel, digitalis and squills, in certain syphilitic conditions is still prescribed.

Addison was the first to prescribe static electricity in the treatment of spasmodic and convulsive diseases (1837), and with John Morgan wrote the first book in English on the action of poisons on the living body (1829). He published an excellent account of appendicitis in 1839.

In 1837 he became physician to Guy’s Hospital. His chief researches were on pneumonia, phthisis and especially on the suprarenal capsules. He wrote on disorders of the female, and, with Dr. Bright, “Elements of the Practice of Medicine.”¹

In 1849 Addison read a paper² describing pernicious anemia and diseases of the suprarenal capsules. These clinical articles were at a later date expanded in his great monograph, “On the Constitutional and Local Effects of Diseases of the Suprarenal Capsules.”³ At the time this work was merely a scientific curiosity. It is now looked upon as epoch making.

Addison described a constitutional affection manifesting itself in an exaggeration of the normal pigment of the skin, asthenia, irritability of the gastrointestinal tract, and weakness and irregularity of the heart’s action; these symptoms being due to loss of function of the suprarenal glands. It was Trousseau who first proposed to call this suprarenal syndrome “Addison’s Disease,” by which it has been known to date.

Addison died at the age of sixty-seven years on June 29, 1860.

STUDIES IN PALEOPATHOLOGY XXV

HYPERTROPHY IN THE SACRUM OF THE SABRE TOOTH, PLEISTOCENE OF SOUTHERN CALIFORNIA

ROY L. MOODIE, PH.D.

SANTA MONICA, CALIF.

OSSEOUS hypertrophy, as seen in the skeletons of fossil vertebrates, may indicate a variety of conditions. Pachyostosis is one of these and represents a non-pathological heaviness developed in the skeleton of vertebrates in response to a number of causes. This phase of paleontology is well known and has been so recently discussed that nothing more need be said about it here. Hypertrophy of bone accompanying a wide range of pathological conditions is also well known so it only remains for us to locate the present example of osseous hypertrophy in its proper place.

Examination of the figures will show that there is a necrosed area on the dorsal surface of the sacrum, to the right of Figure 1. I am going to state that, probably, the tiger to whom this pelvis belonged received a stab wound from the sabres of another tiger which having become heavily infected, resulted in the hypertrophic changes which are so evident in the specimen. The condition seen is thus interpreted as an example of osseous hypertrophy following a violent trauma, subsequently infected. The example is

quite unique and forms a striking object in the series of pathological pelves of the *Smilodon*. The last two lumbar vertebrae, firmly ankylosed to the sacrum, indicate that a slight scoliosis had developed as one of the changes due to the injury. The most striking change is the ossification of all the sacral ligaments, dorsal and ventral, accompanied by hypertrophic changes in the sacral and lumbar vertebrae themselves. I have sought eagerly for hypertrophic changes due to endocrine disturbances, but so far without success. A gigantic skull of a lion, one-third larger than any other lion skull in the collection, suggests pituitary changes; but a careful examination of the endocranial cavity is yet to be made.

The normal sacrum of the sabre-tooth has three vertebral segments, measuring in three specimens from 110 to 120 mm. in length. There are 1086 sacra of young and adult sabre-tooth tigers in the collections of the Los Angeles Museum, all of which I have examined. Only fourteen of them are pathological, and the present specimen is the most extensively changed of any of them. Even in old individuals

the sacrum is not preserved with the pelvic rami. Only three specimens retain this association and all of them are patho-

Changes due to disease are quite extensive in one specimen.

The most striking feature of the dorsal

FIG. 1. Dorsal aspect of hypertrophied sacrum and pelvis of young, though mature, sabre-tooth (*Smilodon californicus*), showing intense ossification of ligaments, following injury, effects of stab wound received in right pelvis. Two lumbar vertebrae are firmly united to sacrum by ossified ligaments. Length of right pelvic ramus 320 mm. Left ramus was broken and part of it is lost. Length of vertebral mass, as preserved 160 mm. Sacrum proper is broken through middle of second segment. There is such firm coossification between sacrum and pelvis that a post-fossilization break took away part of each. Pelvis is otherwise unaffected. (Specimen in the Los Angeles Museum.)

logical. While there is some range in the length and width of the sacra none save the one here described exhibit hypertrophy. Five of them exhibit the phenomenon of sacralization which will be described in another paper.

Except for the slight pathological changes in the crest of the right ramus and its firm coossification with the sacrum and last lumbar, the pelvis is unchanged. A comparison with several pelvises shows a considerable variation in size. The acetabular cavities are unaffected. Pathological conditions in the pelvis of the sabre-tooth will be described elsewhere.

surface of the hypertrophied sacrum (Fig. 1) is the ossification of the vertebral ligaments, especially the Ligamenta interspinale, supraspinale, intertransversarium.¹ The differences between the right and left sides in the ossification of the ligaments may be explained by the presence of the abscess represented by the necrosed area on the right. There are a few blunt exostoses accompanying the ossification of the ligaments. The coossification between the pelvis and the sacrum is very intense.

¹ See Studies in Paleopathology. *Ann. Med. Hist.*, 8: 78; 288, 1926, for explanatory diagram.

Ossification of the ligaments of the lumbar vertebrae is not intense. The slight scoliosis is to be explained by the ossification of the ligaments on the left.

The sacrum had been broken, possibly during excavation, through the middle of the second sacral segment. The broken surface has a transverse diameter of 60 mm., and it is hypertrophied to more than one-third larger than normal. The neural canal is obliterated. This was not serious since, like the modern bob-cat, the sabre-tooth had a very short tail, and the last part of the sacrum contained a sort of cauda equina. The hypertrophy is ascribed to changes following upon a severe injury, subsequently heavily infected.

The ventral surface of the specimen (Fig. 2.) shows intense ossification of the ligaments, largely of the left side. The left transverse process of the last lumbar had been broken during life, and healed.

I think the appearances of the lesions indicate that suppuration had ceased before death. Except for a period of intense pain, following the infection, and some stiffness in the pelvic muscles the

activities of the animal would not have been interfered with by the results of the injury.

FIG. 2. Ventral aspect of same pelvis showing the ossification of ligamentum longitudinale. Anterior surface of lumbar vertebra is unaffected, so that pathological condition may be spoken of as spondylitis deformans.

BOOK REVIEWS

THE DRAMATIC IN SURGERY. By Gordon Gordon-Taylor, O.B.E., M.A., F.R.C.S. 88 pp. 40 illus. N. Y., William Wood & Co. 1930.

The book with this most attractive title is based on an address delivered in Manchester, February, 1928. The contents, like the title, are delightful. There are forty splendid illustrations. As the author well points out "it is often for those morbid conditions which are *infinitely little* rather than for those which are gigantic or colossal . . . that the *most expert*, . . . but perchance the *least dramatic* surgery is really required," and further that: "perhaps Caesarean section proves the greatest source of attraction . . . though, of course not nearly requiring as much expertness as many an operation that would attract little attention on the part of the uninitiated." The author's own

dramatic instinct is indicated by his calling the foreign bodies, which are removed from the *corpus humani*, "trophies," and his reference to "surgical megalomania."

That "the dramatic in surgery may be attained alike by the *elaboration* or by the *simplicity* of the requirements which are regarded as essential to the art," should be impressed upon all students. Simplicity in surgery, as well as in all other arts, is undoubtedly the greatest and most difficult of achievements.

As the most modern touch, he mentions that "as a means of rendering 'first aid' the aeroplane may be valuable." Considering the arrival of the surgeon in an aeroplane as part of "the dramatic in surgery" is in itself rather good theatre.

Humorous instances are not overlooked by

our author and here, as elsewhere, the ubiquitous Scotchman is quoted: "A Scotchman walking down Charing Cross Road on the way to Charing Cross Hospital to have the hydrocele tapped, saw a sixpence on the pavement and stooped to pick it up; he ruptured the hydrocele and was brought to Middlesex Hospital instead."

It must not be thought for a moment that this book is only for amusement or pastime. It contains many an axiom that may well be taken to heart by even the most experienced surgeon, such as "This at least is certain: the most thorough co-operation of surgeon, physician, radiologist, and laboratory worker is necessary to decide the need of surgery and to determine the appropriate character of the operation to be performed." A small book, but well worth while.

THE ACTION OF MUSCLE. By Sir Colin Mackenzie, M.D., F.R.C.S., F.R.S., (Edin.), Ed. 2, 288 pp., 100 illus., N. Y., Paul B. Hoeber, Inc., 1930.

This is the second edition of this widely read work.

Since the Great War greater attention has been paid to the importance of muscle function, whether in the consideration of health or disease, than formerly. Physiotherapy today plays an important part in every modern hospital. In this new edition a special section has been added dealing with the erect posture. The author dealt with these principles in his presidential address before the Section of Zoology at the Australasian Science Congress in 1928.

After the introduction the book considers Principles, The Shoulder Region, The Biceps Brachii and Brachialis; Musculocutaneous Paralysis, Median Nerve Paralysis, Ulnar Paralysis, Musculo-Spiral Paralysis, The Muscles of the Thigh, Muscles Acting on the Leg, Muscles Acting on the Foot, The Muscles of the Toes, Muscles of the Spine, Muscles Which Move the Neck, Muscles Which Move the Back and Loins, Anatomical Considerations in Joint Fixation, The Muscles of Respiration. The book is well indexed and contains 100 illustrations.

Any doctor will profit by reading this important work but we specially recommend it to surgeons and neurologists.

NEUE DEUTSCHE CHIRURGIE. Begründet von P. von Bruns. Herausgegeben von H. Küttner in Breslau. 44 Band. *DIE CHIRURGIE DER BASEDOWSCHEN KRANKHEIT.* Von Dr. Heinrich Klose, Prof. der Chirurgie an

der Universität Frankfurt Am Main; Direktor der Chirurgischen Abteilung des Stadtischen Krankenhauses der Freien Stadt Danzig. 675 pp. mit 273 Teils Farbigen Abbildungen. Stuttgart, Ferdinand Enke, 1929.

45 Band. *DER WUNDSTARRKRAMPF BEIM MENSCHEN.* Von Dr. Arthur Buzello, Prof. an der Universität Greifswald. 276 pp. mit 51 Textabbildungen. Stuttgart, Ferdinand Enke, 1929.

46 Band. *CHIRURGIE DER MILZ.* Von Prof. Dr. H. Hirschfeld, Berlin und Prof. Dr. R. Mühsam, Berlin. 286 Seite mit 32 Teils Farbigen Textabbildungen. Stuttgart, Ferdinand Enke, 1930.

47 Band. *DIE HÄMOPHILIE.* Von Prof. Dr. H. Schloessman, Direktor der Chirurgischen Abteilung der Augusta-Krankenanstalt Bochum. 321 pp. mit 60 Textabbildungen. Stuttgart, Ferdinand Enke, 1930.

Four new volumes of the famous "Neue Deutsche Chirurgie" are before us and as usual each volume is a complete and up to date monograph on its particular subject.

Klose's book on "Basedow's Disease" is the largest of the four and especially well illustrated. With a controversial subject in hand, the author had a difficult time of it. In his Preface he explains that the book does not suit him completely, but that he has acceded to the pressure put upon him by both the editor and the publisher to produce the volume at once. The reviewer feels that the author is entirely too modest and that the book may well be accepted as a comprehensive and thoroughly scientific review of the present status of the etiology, pathology and treatment of this disease. His plea that the surgeon should always work in cooperation with the internist in the treatment of this condition is one that every American surgeon may well take to heart.

The volume by Buzello on Traumatic Tetanus covers, as the author states, one of the most important and terrible wound infections with which we have to deal. Tetanus is considered as a bacteriological infection and also as a nervous disease, so that the book will also interest the clinician. The author feels that as tetanus usually follows wound infection, its treatment will continue to be in the hands of the surgeon, especially as such an infection involves important and serious surgical operations. Here again, as in the other volumes of the series, the necessity for cooperation between the physician and surgeon is particularly stressed, even though the ultimate treatment is felt to be entirely surgical.

Hirschfeld and Mühsam take up the present status of the surgery of the Spleen. It is interesting to note that whereas this volume on

the Spleen has 286 pages, the volume on this subject in the "Deutsche Chirurgie" published in 1890 contained only 57 pages. In the last forty years progress has indeed been made in the surgery of the spleen, and its removal is today advised for many other conditions beside tumors of the spleen. Here again, as in the volumes mentioned here, the authors make a plea for the utmost cooperation between the surgeon and the internist. Up to the minute, thorough and profusely illustrated, this volume will be invaluable for reference to German reading surgeons.

Hemophilia is discussed in 306 pages by Prof. Schloessmann, who has had unusual opportunities for research in this condition during many years at Württemberg. This work contains an unusual amount of personal research and conclusions drawn therefrom, combined however with a complete study of the international literature on the subject. Like our American writers, the author feels that most progress in the prevention of this disease will come from a more thorough study and knowledge of eugenics. The book is fully up to the standards of the other volumes of this series.

All the volumes of the "Neue Deutsche Chirurgie" contain splendid bibliographies. It is to be regretted, however, that each volume has not a detailed index. They all have comprehensive table of contents, but a complete index would facilitate ready reference.

MODERN OTOTOLOGY. By Joseph Clarence Keeler, M.D., F.A.C.S. 878 pp., 90 original illus. and 15 colored plates. Phila., F. A. Davis Co., 1930.

There is nothing so difficult to review fairly as a textbook. It should bear the stamp of the author's individuality; at the same time it should not feature any of his hobbies too strongly. Like other methods of teaching, it is not a question of whether one agrees with the particular method used, but of the success attained in getting the subject across to students. Dr. Keeler recognizes this difficulty when he states that "During many years of otologic practice and preaching . . . I have always felt that the existing textbooks were unsatisfactory. Though their good points outnumbered their faults . . ." And he adds "When, occasionally, I voiced this dissatisfaction . . . the advice I usually received was: 'Write a book yourself.'" Now, of course, his own book must submit to the same attitude on the part of

others. The subject is completely covered, the illustrations are well selected and well reproduced; in short we have before us another good, conventional, textbook. That it will appeal to many teachers and students is certain; that it will not suit everybody is equally certain. Were there not differences of opinion there would be occasion for only one textbook on each subject, a condition that is often prayed for by teachers, students and publishers. On the other hand, the very variety of books, forcing critical selection, undoubtedly makes for better teaching, better textbooks, and better practice. Every otologist will want this book if only for comparison with others. The man having only one book on otology will not go far wrong if he selects Keeler's "Modern Otology," and the same could be said of several other books on the subject.

A SHORTER SURGERY. A Practical Manual for Senior Students. By R. J. McNeill Love, M.B., M.S. (Lond.), F.R.C.S. (Eng.) Ed. 2, 389 pp., 74 illus., including 31 plates (one colored). N. Y., William Wood & Co., 1930.

This book lives up to its title: "A Shorter Surgery." For a quick freshening up on the general subject for examination or otherwise this work should be valuable. The author states that it "is an attempt to condense and crystallise the more important principles of surgery for the benefit chiefly of the student." Whether it is too short for the student is a problem that the individual instructor will have to decide for himself. It appeals to the reviewer more as a quick reference for the experienced surgeon. In any circumstances it can be considered only a supplement to larger textbooks. The book is well illustrated.

THERAPIE UND THERAPEUTIK: EIN MAHN RUF AN ÄRZTE, KLINIKER UND PHARMAKOLOGEN. By Prof. Dr. I. Boas. vi + 79 pp. Verlag von S. Karger, Berlin, 1930.

It is encouraging to note that the great German precisionistic movement in science which swept through medicine during the last fifty years has at last embraced therapeutics. Dr. Boas makes an impassioned plea for scientific therapeutics studied under controlled conditions as immediately necessary if medicine is ever to get over the barren wastes of a traditional therapy. The plea is timely for Germany, where commercial exploitation is making a mockery of the treatment of disease. Thanks to the "therapeutic nihilism" of Osler and the weighty influence of the Council on Pharmacy and Chemistry of the American Medical Asso-

ciation, American medicine has long been developing a healthy interest in real scientific therapeutics. Dr. Boas might have used our experience to advantage in his thesis. At any rate, we may watch the effect of his "warning" with sympathetic interest.

STRAHLENBEHANDLUNG DER WEIBLICHEN GENITAL-CARCINOME, METHODEN UND ERGEBNISSE (Radiation Therapy of Female Genital Carcinoma, Methods and Results). By Prof. Dr. Friedrich Voltz, Dir. Radiotherapy Section, Gynecol. Clin. Univ. of Munich, with foreword by Geheimen Rat Prof. Dr. Albert Doderlein, Dir. Gynecol. Clin. Univ. of Munich. 57 colored illus., 8 colored charts and 40 tables. Berlin, Urban & Schwarzenberg, 1930.

This 206 page work represents a real contribution to our present knowledge of methods and results of radiotherapy in the treatment of genital carcinoma of women. The work done in this field by the Doderlein Clinic of Munich is well known to every gynecologist and radiologist doing gynecological radiotherapy. Professor Doderlein made his first very important report on this subject from his clinic in 1913 before the International Congress of Medicine in London.

There is a brief chapter on the development of radiation therapy of female genital carcinoma. The second chapter deals with the effort being made by the Hygienic Section of the League of Nations to forward the progress of the campaign against carcinoma. In fact this book really represents a report by Professor Voltz, as a member of the sub-committee of the League of Nations, Hygienic Department, appointed to investigate genital carcinoma in women.

The author gives a classification of carcinoma of the female genital tract, with many beautiful colored illustrations of the histological appearances, followed by a description of the roentgen apparatus for deep roentgen therapy, the apparatus for measuring dosage, and a description of the necessary supply of radium and radium applicators for gynecological radiotherapy.

The general method of treatment which is pursued at present in the University of Munich Gynecological Clinic is as follows:

First day: Examination of the patient, taking of the history, and study of the various clinical findings, and marking out of the various parts of entry ready for the treatment.

Second day: Radiation over the hypophysis. This was first suggested by Henry Hirsch and since the year 1923 has been part of the routine

treatment of all carcinoma patients in the Munich Clinic. The idea is to sensitize the carcinoma. The author has seen no disadvantage from this treatment; on the contrary he is quite convinced that the general condition of the patient has been very much improved during the radiotherapy. Two lateral fields are employed, 6×8 cm. The focal skin distance is 30 cm. and the treatment amounts to 30 per cent of the erythema dose at 200 kv., with 2.5 ma. and 1 mm. of copper filter. This treatment is given only once at the time of the first series of treatment.

Third day: The patient is given an injection of "Dextrocid," following which the physician goes ahead with the general radiotherapy to the pelvis. This "Dextrocid" injection is an intravenous administration of glucose, which has been done routinely in all their cancer cases since 1927. It also was introduced by Henry Hirsch in Hamburg. The author claims to have seen beneficial results following this injection.

Fourth day: The fourth day is rest day. Sometimes more than one day is necessary.

Fifth day: On the fifth day is done any diagnostic work necessary, such as the excision of specimens, or of extrafoliating tissue, or the cauterization or cataphoretic treatment as may be necessary.

Sixth day: The sixth day is rest period which may be extended if necessary.

Seventh day: Glucose injection and treatment with radioactive substances.

Eighth day: The eighth day is rest day.

Ninth day: Discharge of the patient.

The second series of treatment occur after an interval of eight weeks from the day of the discharge of the patient. The third series may sometimes be given after another interval of eight weeks.

The result can hardly be reported in a review. The authors not only give their own results but they summarize the results published from numerous sources both in Europe and in America. They conclude by expressing the hope that this work, with its published results, will further emphasize the declaration of Professor Doderlein that the radical operation for uterine carcinoma is no longer justifiable.

Concluding chapters are translations of reports from the Radium Hemet of Stockholm by Heyman and from the Radium Institute in Paris by Lacassagne and by Regaud.

TRAITÉ DE RADIODIAGNOSTIC, Squellette en General (Tete-Rachis-Bassin-Membres). By G. Chaumet, Ass. Prof., Val-de-Grace, Paris. 202 figs. Paris, Vigot Frères, 1930.

This 350 page treatise on the x-ray diagnosis of bony lesions is the result of the author's belief that it is well to bring together periodically the well established facts and from them to take stock of our resources. To rejuvenate old ideas, to eliminate certain lines of effort which seem useless, to moderate enthusiasm for methods or theories which appear to be too popular, to offer a critical analysis of results in the light of experience, and to make a slight personal contribution, these are the reasons given by the author for his book.

All progress is achieved at a price. The perception of bones through soft tissues carries with it a certain number of illusions: the deformities, enlargements, superposition of shadows due to the conical projection of the x-rays, all the optical phenomena which lead to error. It is the duty of the radiologist to profit by investigation in new improvements of technic and by the employment of new positions and angles of incidence.

The patient presents numerous individual problems. The reading of the radiographic films cannot be correctly done without a certain familiarity with pathology. But even the best possible film cannot be judiciously interpreted by the most distinguished physician in the world if he lacks the necessary training.

The task of the medical radiologist rests upon a triple foundation: (1) Adequate radiographic technic; (2) abundance of experience in interpretation; (3) a broad medical training.

After a brief consideration of general principles and a chapter on the radiographic appearances produced by various morbid processes in bone, the author proceeds to a regional discussion of bony lesions as revealed in the radiographic films. There is an excellent outline for the study of bones. Numerous illustrations add value to the suggestions as to improvements of technic. Various positions are advised which, though not in common use, merit careful consideration and more frequent employment.

U. GALLBLADDER DISEASE, Roentgen Interpretation and Diagnosis. By David S. Beilen, B.S., M.D., Roentgenologist, Augustana Hospital, Chicago. St. Paul, Bruce Pub. Co., 1929.

There is much about this work to commend it. There are large, well reproduced illustrations, rich in radiographic detail. The text,

though meager, presents the clinical and pathological facts in order, with the x-ray evidence as a series of films for each case. The work should prove helpful in the interpretation of oral cholecystography. The author dismisses with a few words the intravenous method as of little importance, although Graham and his associates, after many thousands of trials of both oral and intravenous administration of the tetraiodophenolphthalein, still emphatically advise the intravenous route as more reliable. As an exposition of the views of one who is entirely satisfied with the oral method and claims an unusually high percentage of operatively proved accuracy, this work is an admirable product.

TASCHENBUCH DER MEDIZINISCHEN RONTGEN-UND RADIUM TECHNIK. By Dr. Phil. Gottfried Spiegler and Dr. Phil. Albert Fernau, Leiter der Rontgentechnischen Versuchsantalt am Zentralrontgeninstitut des Allgemeinen Krankenhauses in Wien and Privatdozent fur medizinische Physik und Chemie des Radiums an der Universität Wien, respectively. 330 pp. and 63 illus. Wien, Julius Springer, 1930.

An excellent brief introduction to the practice of radiography and radium therapy. The book abounds in tables, formulae and rules for protection. There is much detailed information regarding minor points of technic included in this systematic consideration of the physical and practical bases of radiologic diagnosis and therapy.

X-RAY TECHNOLOGY, The Production, Measurements and Applications of X-Rays. By H. M. Terrill, Ph.D., Assoc. in Physics, Inst. Cancer Research and C. T. Ulrey, Ph.D., Research Physicist, Westinghouse Lamp Co. N. Y., D. Van Nostrand Co., Inc., 1930.

The authors state that in preparing this book it has been their purpose to present the practical rather than the theoretical aspects of x-ray measurements as they are inevitably encountered by all who choose to work in the x-ray laboratory. Much of the contents is devoted to problems common to all x-ray laboratories but particular attention has been given to the quantitative measurements involved in roentgen therapy and in the application of the x-ray to industrial problems. A considerable portion of the contents may be properly classified as x-ray engineering.

Properties of moving electrons are discussed in 25 pages, x-ray tubes and their operation in 50 pages, generators of high voltage in 20 pages. Pages 99 to 211 discuss measurements of voltage and current, ionization, total energy,

wave-length and biological problems. The remaining 40 pages are devoted to x-ray analysis and radiography, especially in its industrial applications.

This is a very readable, interesting book and well worth acquisition by all interested in radiology.

YOURSELF, Inc., *The Story of the Human Body*. By Adolph Elwyn 332 pp., 71 illus., N. Y., Brentano's, 1930.

The title of this book will undoubtedly appeal to those whom it is intended to attract. To the reviewer the sub-title "The story of the Human Body" is much more attractive but "wise-crack" titles seem to be the order of the day and if "Yourself, Inc." will draw additional attention to the story of the human body so much the better for the readers, for the author, the publishers and for the medical profession. The story is well told, accurate and definite, and may be recommended without compunction to every intelligent layman. Scientific facts are put before him in language that he will readily understand but which, at the same time, assume more common sense on the part of the reader than many authors of so-called "popular medical books" are in the habit of accrediting to him. The first chapter, regarding the title of which there seems to a difference of opinion between the caption writer and the index maker (for it is indexed as Looking Backward and the running head reads Looking Back), is a delightful fifteen-page abstract of the History of Medicine to the time of Vesalius and Harvey. The other chapters in turn are headed Introducing the Body, Concerning the Cell, The Living Membranes, The Building Trades and Their Strange Associates, The Transport Workers, The Pump and Engine Workers, The Engines of the Human Body, The Transportation System, The Food and Fuel Industries, The Utilization of Air, The Disposal of Garbage, The Central Government, The Central Government (continued), The Regulation of Home Activities, Concerning Reproduction, Looking Forward. The author is very apt in his ability to draw an analogy between the workings of the human body and those of machinery.

CHIRURGIE DES KINDESALTERS. By Prof. Dr. R. Drachter and Dr. J. R. Gossmann. 1047 pp., 714 illus., Leipzig, F. C. W. Vogel, 1930.

This new edition has been brought entirely up to date as is evidenced by the mention of

Intravenous Pyclography. Incidentally, attention is called in the Preface to the fact that the portion on the urinary tract has been completely revised. The illustrations, both colored and black and white, leave nothing to be desired, and the text of over 1000 pages covers the subject thoroughly and without padding. It is an invaluable book on Surgery in Children that is indispensable to every German reading surgeon.

THE INTERNATIONAL MEDICAL ANNUAL: A Year Book of Treatment and Practitioner's Index. Editors: Carey F. Coombs, M.D., F.R.C.P. and A. Rendle Short, M.D., B.S., B.Sc., F.R.C.S. 609 pp., 61 pl., 54 illus., N. Y., William Wood & Co., 1930.

The annual return of the International Medical Annual is as welcome as are the flowers that bloom in the spring. Particularly for the man who "has not the time" to keep up with the voluminous literature appearing each month, this annual resume of the advances in medicine is a boon. With the death in April of last year of Dr. Wilde, its founder and editor, the new volume has been taken up by Drs. Coombs and Short, as editors, and the old traditions have been well preserved. Unusually well illustrated, this volume forty-eight presents, as do the previous ones, a compact and reliable review of the medical and surgical advances of the year.

DAS FÜR UND WIDER DER CHIRURGISCHEN BEHANDLUNG DES GALLENLEIDENS auf Grund der Erfahrungen an 800 Gallenoperationen. By Prof. Dr. Paul Zander, Chirurg des Elisabethenstifts in Darmstadt. 95 pp., 8 illus., Leipzig, Georg Thieme, 1930.

This eighty-nine page consideration of the perennial discussion concerning the medical and surgical treatment of gall bladder diseases presents both sides tersely. It comes, as do all such discussions, to the inevitable conclusion that the ideal situation is honest cooperation between the internist and the surgeon. The debate of this subject will continue for a long time and it is interesting to have this resume which really presents the present status of the case.

MERCK'S INDEX: An Encyclopedia for the Chemist, Pharmacist and Physician, Giving the Names and Synonyms; source, origin, or mode of manufacture; chemical formulas and molecular weights; physical characteristics; melting and boiling points, solubilities; specific gravities; medicinal action; therapeutic uses; ordinary and maximum doses; incompatibilities; antidotes; special cautions; hints on keeping and handling, etc., of the Chemicals and Drugs Used in Chemistry, Medicine and the Arts together with an Appendix containing: reactions of the more important alkaloids

and glucosides; characteristic reactions of acids, bases, metals, and salts; table of atomic weights; thermometric equivalents; specific gravity tables; metric conversion tables; and abbreviations. Ed. 4, 593 pp., Rahway, N. J., Merck and Co., Inc., 1930.

The third edition of this work was published in 1907 and it is explained that the delay in the publication of the fourth edition "was caused largely by the complete interruption of work on the book in both laboratory and editorial rooms during the World War." That the book lives entirely up to its title (as given here) is perhaps the best description that can be made of it and it is a high compliment indeed. It is believed that the hope expressed in the Preface "that it will meet the needs of the student, the apprentice, the young man on the threshold of his professional career" will be entirely fulfilled.

OBSTETRICS FOR NURSES. By Joseph B. De Lee, M.D., Ed. 9, 645 pp., 269 illus., Phila., W. B. Saunders Co., 1930.

The new ninth edition of De Lee's *Obstetrics for Nurses* deserves its widespread popularity.

In this edition many new features are included. The book has been carefully revised, completely reset and contains hundreds of new illustrations.

One can understand why this is the standard textbook in the large majority of training-schools for nurses. We might add, the type of general practitioner who has little time for quiet study and reading, who is rusty in the ordinary fundamentals of obstetrics, can read this book with mental and practical profit.

GYNECOLOGY FOR NURSES. By George Gellhorn, M.D., 275 pp., 145 illus., 12 mo., Phila., W. B. Saunders Co., 1930.

This is a book that should receive a welcome in every training-school for nurses. It is a good book from every angle. Dr. Gellhorn is especially fitted to have done this work. He has taught nurses for over twenty years. He knows what a nurse needs in the performance of her duties. In his *gynecology for nurses* as held to the sane and practical. He has left out the pseudo-scientific hokum, so noticeable in many works for nurses that are made into big books by unnecessary padding.

This book covers the subject. It is easily read. Any nurse is sure to grasp the thoughts conveyed by the author. It has 275 pages and 145 illustrations. We do not only cheerfully recommend it but we urge that it be in the hands of every pupil nurse.

DISEASES OF THE NOSE, THROAT AND EAR, Medical and Surgical. By William Lincoln Ballenger, M.D., F.A.C.S., and Howard Charles Ballenger, M.D., F.A.C.S. Ed. 6, 1138 pp., 583 engravings, 29 plates, Phila., Lea & Febiger, 1930.

The sixth edition of this work, revised by Howard Charles Ballenger, has become a formidable treatise of over 1100 pages and 600 illustrations. Drs. Tucker and Jackson have written the part on Bronchoscopy, Esophagoscopy and Gastrosocopy. The chapter on the Labyrinth has been rewritten by Dr. Alfred Lewy. Other changes and revisions throughout the book have brought it up to date and it should retain for many years its position as one of the standard works of reference in its field.

UEBER RÖENTGENSCHAEDEN UND SCHAEDEN DURCH RADIOAKTIVE SUBSTANZEN. By Priv.-Doz. Dr. Wilhelm Flakamp, Gynecological Clinic, Univ. of Erlangen. 365 pp., 94 illus., 30 half-tone plate illus. and 6 tables. Berlin, Urban und Schwarzenberg, 1930.

Just what we have been looking for! A collection of all the known facts concerning the possible damage resulting from the use of roentgen rays and other radioactive sources. This mine of information will undoubtedly find its way very soon into the library of every member of the legal or medical profession who has an active interest in x-ray damages and the legal action which so often attend them. From the scientific point of view the work is also a rich repository of facts gleaned from the literature of the world. The book is illustrated with numerous photographs, some of them series of pictures of the same case taken during the life of the patient and therefore constituting a document of unusual worth.

The first section deals with a brief historical statement, the various theories relating to the mechanism of damage to the skin from x-ray exposure, and a very detailed study of the biological and histological manifestations of roentgen erythema and dermatitis, treated from every possible point of view. Other high lights are sections on roentgen carcinoma, roentgen ulcer, telangiectasis, and the prophylaxis and treatment of roentgen dermatitis.

The second section concerns damage from x-rays to the deeper tissues and the internal organs, including in turn a consideration of the subcutaneous tissues, muscles, bones and joints, the teeth, serous membranes, the lungs, larynx, intestines, the urinary tract, brain and central nervous system, the eyes, the glandular organs (thyroid, thymus, hypophysis, pan-

creas, liver, etc.). Liberal space is given to the effects upon the generative organs of men and of women, and especially the influence of irradiation upon pregnancy. Final sections are devoted to the blood and the blood-building organs, and general roentgen reactions. Very full lists of references to the literature terminate this very important contribution to the literature of radiation therapy.

DIE RÖNTGEN-LITERATUR Autoren- und Sachregister Patentliteratur. Herausgegeben von Dr. Hermann Gocht. VIII Teil, 1927, 350 pp. IX Teil, 1928, 384 pp. Stuttgart, Ferdinand Enke, 1928, 1929.

The eighth and ninth volumes of Gocht's annual bibliography of radiological literature present a picture of the work done in radiology in 1927 and 1928. The literature of all languages seems to be thoroughly covered. Everyone interested in radiology owes a debt of gratitude to both Dr. Gocht and his publishers for making available annually in a handy volume a bibliography of this increasingly important subject.

A fairly careful check-up reveals few errors or omissions. The book arouses in the reviewer a wish that a similar bibliography could be published on every specialty of medicine. The finding and checking of references would indeed be simplified.

RÖNTGENUNTERSUCHUNGEN AM INNENRELIEF DES VERDAUUNGSKANALS von Dr. Hans Heinrich Berg. Ein Beitrag zur klinischen Roentgendiagnostik Insbesondere Von Entzündung, Geschwür Und Krebs. 193 illus., Leipzig, Georg Thieme, 1930. Price, paper 27 m., bound 29 m.

One of the evolutions which has been taking place in diagnostic radiology concerns the more accurate study of the lining of the alimentary tract. This was first accomplished, as is well known, by opaque materials introduced into the stomach, accomplished in 1897 by Cannon and Williams in Boston and then 1908 popularized by Rieder in Munich. This method

undoubtedly opened up an entirely new field in diagnostic radiology and has resulted in an accuracy of diagnosis exceeding that of all the other laboratory methods combined. There are, however, further refinements which have been achieved by Forsell, Schwarz, Barclay, Akerlund, Baenisch, Chaoul, Milani and Fischer. All of these men have sought to so modify the original opaque-meal technic as to bring out details of the mucous membrane in various segments of the alimentary tract.

The present work relates somewhat briefly the historical development of the method and the apparatus with which the author's studies were carried out. Forsell, Barclay, Akerlund and Schwarz sought to make manual pressure against the anterior abdominal wall to bring out the details of the gastric rugae. Fischer sought to accomplish the same thing by the introduction of air, with the ingestion or injection of just a small amount of contrast material. Baensch, Chaoul and the present author have been leaders in the improved technic of securing mechanical firm pressure against the abdominal wall over the segment of the alimentary tract under study. Holzknecht sought to do this by means of a wooden distinator, with which pressure was made by the hand while the film was being exposed. The later authors have accomplished this pressure by means of a balloon-belt apparatus, which was strapped around the patient. The balloon is then inflated until fluoroscopically it is seen that the proper amount of pressure is being made in the proper place, and then films are exposed. The resulting films reveal an astonishing wealth of detail regarding the mucous lining of the various portions of the alimentary tract, so that the method constitutes a distinctly valuable supplement to the current methods of barium diagnosis. The 193 illustrations in this book comprise a very fine library of reference roentgenograms, valuable to any diagnostician interested in gastroenterology.

Subscribers to THE AMERICAN JOURNAL OF SURGERY visiting New York City are invited to make the office of the publishers (Paul B. Hoeber, Inc., 76 Fifth Avenue, New York) their headquarters. Mail, packages or bundles may be addressed in our care. Hotel reservations will gladly be made for those advising us in advance; kindly notify us in detail as to requirements and prices. List of operations in New York hospitals on file in our office daily.

SECTION I. THE CAVITY

F. PRESSURE VARIATIONS WITHIN THE ABDOMEN (*Continued*)*

5. EFFECTS OF INTRA-ABDOMINAL FAT. Aside from the viscera with the liquids and gases they contain the chief content of the abdominal cavity is fat. Intra-abdominal fat, stored within mesenteries, ligaments and extraperitoneal spaces, acts as padding and serves to strengthen natural supports. Changes in the amount of this fat, as any change in the contents of the cavity, must be compensated for in some way. It has been shown, both clinically and experimentally, that when there is a marked loss of intra-abdominal fat, there follows a compensatory atonic dilatation of hollow viscera, particularly of intestines.⁹² Digestive and asthenic symptoms following an illness attended by a marked loss of weight may be accounted for in many instances by the loss of intra-abdominal fat and the secondary changes attendant upon this loss. The restoration of fat, because it strengthens mesenteric supports and causes a return of dilated gut to normal, is an important post-operative measure.

A large umbilical or incisional hernia which has existed for a long time in a fat individual contains, in addition to other structures a deposit of fat. The amount of this fat tends to be in direct proportion to the size of the hernia. This overproduction of tissue may be so great as to make it difficult if not impossible to return all of the herniated mass to the abdominal cavity. Many complications may be avoided by securing in such patients a decided reduction in weight during

Preoperative Reduction in Weight with Large Ventral Hernias

* Previous installments of this book appeared as follows: January issue, p. 193; February issue, p. 459; March issue, p. 693; April issue, p. 92; May issue, p. 1110.

an extended period of preoperative treatment. It has been said that if a weight reduction of 20 or more pounds can be obtained in patients having large ventral hernias, there will be little difficulty in securing complete reduction of the mass, and that postoperative complications will be appreciably less.¹¹⁵ The high mortality following operation for large ventral hernias may be explained, at least in part, by the overcrowding of the cavity after abdominal closure.

6. EFFECTS OF GRAVITY. Gravity is most important among the factors which determine pressure variations within the abdomen. In the upright position the movable organs, generally speaking are approximately 3 cm. lower than in the prone position.¹¹⁶ The organs lie in actual contact with one another, the upper being partially supported, as on a cushion, by the organs below. On account of the specific gravity of the viscera, the static pressure in the most dependent portions of the abdomen is considerable. The Fowler, knee-chest, and Trendelenburg positions and the elevation of the foot of the bed all illustrate common uses of gravity to alter intra-abdominal conditions.

An effect of gravity is noted in the spontaneous reduction of a hernia when the patient assumes a recumbent posture. The patient using a truss learns that it is of advantage to keep this device near the bed and to apply the truss before arising in the morning thereby being sure of a complete reduction and retention of the hernia. The visceroptotic patient may have learned the same regarding the application of his belt.

The Knee-Chest Position

That a change of posture results in a change in static pressures explains the condition known as "garrulitas vulvae." When the female patient assumes the knee-chest position, pressure is removed from the vaginal vaults as the movable organs of the pelvis and lower abdomen gravitate toward the diaphragm; and when the labia are separated air is admitted to the vagina; when the upright position is resumed a noisy expulsion of air takes place as the static pressure is restored in

the lower abdomen and the vaginal capacity is again reduced. Opening the vulva to admit air is an important, though frequently neglected part of the knee-chest exercise (see eponym:

FIG. 85. The knee-chest posture. Note distention of vagina with air as labia are separated.
(From Sims.)

Marion Sims);¹¹⁷ so also is the taking of deep inspirations while in this position (combining the upward pull of gravity in the reverse static position with the upward pull or suction caused by subdiaphragmatic negativity). A woman assuming the knee-chest position may derive certain benefits therefrom, but will probably gain more through admitting air to the vagina and still more when adding deep breathing to the exercise (Fig. 85).

The relationship between local static pressures and general intra-abdominal pressures may be illustrated as follows: the

fundus of the uterus may rest forward upon the bladder or backward upon the rectum, causing in one instance bladder, and in the other, rectal-pressure; yet obviously the position of the uterus can have little bearing upon any pressure which may be present within the abdomen as a whole.

The Habitus
Enteropticus

7. EFFECTS OF INDIVIDUAL HABITUS. The habitus of the individual, particularly with regard to the shape of the lower thorax, and the erectness of the spine (a narrow chest and a forward curvature of the spine serving to diminish abdominal capacity) plays an important rôle in determining the character and distribution of abdominal pressures. Individuals with narrow, flat chests and sharp intercostal angles (habitus enteropticus) exhibit markedly different intra-abdominal arrangements from those of the square-chested type. Patients with congenital visceroptosis display a constitutional weakness in supporting tissue.¹¹⁸ This is noted by the malposition of one or many organs, the partial or complete failure of normal embryonic rotations and fusions in the gastrointestinal canal and the continuous display of subjective abdominal symptoms of a distressing nature. There seems also to be an excessive tendency to the formation of intraperitoneal adhesions. The small capacity of the upper abdomen crowds the viscera to abnormally low levels and produces lengthening and traction upon intra-abdominal supports, thus markedly accentuating such symptoms as are caused by any downward displacement of the organs. The abdomen presents an s shape, being flat or retracted above and protuberant below (Fig. 86).

Subjective Symp-
toms from Vis-
ceroptosis

Subjective symptoms are due chiefly to stretching and irritation of the splanchnic nerves and vagi together with torsions and pressures upon local blood vessels. These range from the dull gnawing feeling within the epigastrium and the slight faintness or giddiness experienced after going for a long period without food, to the severe grades of gastrointestinal, cardiovascular, pulmonary, nervous and nutritional disturbances, noted with marked visceroptosis, constituting the sympathetic imbalance of a true Glenard's disease.¹¹⁸

Visceroptosis represents one of the most important of surgical studies. Though common, this condition all too frequently remains unrecognized and the patient may pass through many

FIG. 86. Contour of the abdomen with marked visceroptosis. (From French.)

hands, both medical and surgical, before recognition is taken of the stigmata present. Patients having the acquired form of visceroptosis complain chiefly of gastrointestinal symptoms while those with the congenital type of this condition are, as a rule, classed as neurasthenics. The symptoms, which are most varied, may simulate several abdominal diseases and lead to operative intervention which usually proves disappointing as to end-results.¹²⁰ A report has been given concerning 1000 such patients, averaging two and one-half operations each, but presenting a chain of baffling symptoms and syndromes which were little influenced, unless exaggerated by operation. It is not implied that with visceroptosis operations are always contraindicated but they should certainly be undertaken only after due deliberation, and the results should be interpreted in terms of the developmental stigmata which underlie the condition.

Methods for
Visceral Elevation

The subjective symptoms due to displacement of viscera are, as a rule, promptly relieved by support, if this adequately replaces the viscera. Relief is less certain with the congenital than with the acquired type of visceroptosis, because in the former, the shape of thorax and abdomen makes complete replacement difficult or impossible, and the nervous symptom-complex is of such long standing as to be more or less fixed in degree. Measures aimed at a replacement of the organs include¹¹⁸⁻¹²⁰ sleeping with elevation of the foot of the bed; regular assumption of the knee-chest, Trendelenburg, or some other reverse-static posture; prolonged rest in bed with the administration of a fattening diet calculated to shorten ligamentous and mesenteric supports; the use of mechanical binders and straps; the employment of special athletic exercises; and occasionally, operative shortening or rearrangement of abdominal supports. The extent and type of treatment naturally will vary with the severity of symptoms. Treatment, of whatever type, tends to prove quite ineffective unless the viscera are actually elevated and are so supported as to remove downward traction; but when this is efficiently accomplished, prompt relief may be anticipated. The natural support given the organs by the pregnant uterus often grants the visceroptotic woman a period of relief from symptoms and demonstrates the value of adequate elevation and visceral replacement.

RECAPITULATION CONCERNING INTRA-ABDOMINAL PRESSURES. Pressure changes within the abdomen are complex. To assume a close analogy as to pressure conditions between abdomen and thorax must lead to errors. The thorax has a special anatomical composition (rigid walls) to allow for a special physiological activity (respiration) which is entirely dependent upon a reasonably constant relationship between the pressure within and that of the atmosphere. Intrapleural pressure is little effected by gravity, by variations in fat content or size of viscera, or by many other factors which have been seen to play so important a rôle in determining pressures

within the peritoneal cavity. Neither abdominal structure nor abdominal function implies a uniform pressure throughout the peritoneal cavity nor any constant pressure range within this potential space.

The meaning of the term intra-abdominal pressure is necessarily somewhat vague. It is not incorrect to refer to increased intra-abdominal pressure where, by a sudden contraction of the muscular walls, any previously existing pressures are grossly increased; or again, where there is a bulging of the walls from some obvious, generalized and considerable elevation of pressure. An analogous generalized and marked pressure-decrease may be spoken of as a reduction in intra-abdominal pressure. But it must be borne in mind that pressure conditions within the abdomen are a combination of intraperitoneal pressures, static pressures, and intravisceral pressures; and that changes and adjustments are continually being made.

Basically the mean intra-abdominal pressure tends to be equal to that of the atmosphere, for the abdomen, a non-rigid sac, is directly subject to atmospheric pressure and its walls tend passively to bulge outward when the pressure within exceeds that of the atmosphere (ascites; paralytic ileus) or to passively move inward when the pressure within is below that of the atmosphere (dehydration; cachexia). But the abdomen is a muscular sac capable, by voluntary contraction of its walls, of suddenly increasing any pressure within (cough) and by continued involuntary contraction (reflex rigidity) of maintaining such increased pressure; the muscles also, through vital reflex phenomena, may relax and thus decrease intra-abdominal pressures (abdominoenteric reflex). Because of the location of the abdomen, separated from the pleural cavities only by a thin musculofibrous membrane, the upper portions of the peritoneal cavity display a slight reflected negativity (subatmospheric pressure or tension phenomenon) showing the presence of an upward pulling force. Because of location, also, the intra-abdominal pressures show variations

with the phases of the respiratory cycle; and these, in turn, are influenced by the habitus of the individual and his type of breathing, the relative negativity in the upper peritoneal cavity being greatest when breathing is of the thoracic type and during the inspiratory phase of the respiratory cycle, and least when breathing is of the abdominal type. Abdominal pressures, again, vary continuously with changes in intra-visceral pressures (those within individual organs). Any change in pressure within one organ is, of necessity, compensated for by changes in other abdominal viscera or in the abdominal walls. Gravity also is a most important controlling factor in determining pressure variations within the abdomen.

When the surgeon means specifically to refer to intra-visceral or intraperitoneal pressures, or to those due to gravity (static pressures) he should, when possible, so state. The success of diagnostic methods and therapeutic measures which are in any way dependent upon pressure variations within the abdomen will tend to bear a direct relationship to the accuracy with which the true causes of the pressure variations are interpreted.

SECTION II

THE GASTROINTESTINAL TRACT

THE abdomen has thus far been considered simply as an empty space. It has first been investigated as a cavity devoid of viscera and emphasis has been placed upon the interrelationships between the abdomen and other parts of the body. That perspective has been sought which would ensure the truest understanding of the cavity as a whole. And now, by a closer approach, attention will be directed to the abdominal contents and intra-abdominal organs will be individually studied.

As attention is thus withdrawn from the abdominal walls interest at once centers upon the gastrointestinal tract. The enteric canal with its voluminous intestinal loops and massive glandular outgrowths practically fills the abdomen (Fig. 87). It has a length equal to from five to six times that of the body itself. Alike by fact and by derivation of terms the intestines constitute the "inwards" or the "insides" of the belly (L. *intus*, within) (entrails, L. *interaneus*, internal, inward, interior). As is readily apparent the space within the abdomen is given over almost entirely to processes of alimentation (L. *alimentum*, food, nourishment). This extreme length of the alimentary canal represents an adaptation to function. Digestion (L. *digerere*, to dissolve or divide) is in part chemical and in part mechanical and this necessitates the provision of a large lymphatic and vascular absorptive area and of adequate storage space both for foods and waste products. Occupying the major portion of the abdominal cavity the gastrointestinal tract becomes a major consideration in any review of this space.

It seems quite generally agreed that there is but one logical point at which to begin a broad investigation of this tract, namely with a study of its origin. Embryology has proved the most reliable guide in explaining adult conditions.

FIG. 87. Note that the enteric canal with its voluminous intestinal coils and massive glandular outgrowths practically fills the abdomen. (From Cunningham.)

Anatomical and physiological considerations which might otherwise remain almost inexplicable are rendered relatively simple through a study of the development of the digestive tube. Many observations made at the bedside and many manouvers suggested for the surgical amphitheater are rendered clearly intelligible only through insight into the series of changes which take place during embryonic life.

In the present post-graduate review, therefore, no short-cut will be attempted from this somewhat laborious method of tracing step by step succeeding developmental alterations, for the inevitable reward is a more clear understanding of both diagnostic and operative matters. A clinical review, it might be pointed out, has as its immediate aim only the study of points which are essentially practical. But to fully appreciate bedside observations some fairly accurate knowledge must first be had of the mechanism by which signs and symptoms are initiated. Correct diagnostic conclusions are necessarily dependent upon a correct interpretation of the diagnostic data. In succeeding pages, then, there will be combined and correlated in the most intimate fashion topics which are elemental and basic with those which are purely clinical in character and the attempt will be made, not only to discuss the clinical observations themselves, but in addition to take up the manner in which they may be produced and to suggest ways in which they may be accounted for.

A. BASIC EMBRYOLOGICAL CONSIDERATIONS

The abdominal portion of the body consists fundamentally of a tube suspended within a tube (Fig. 88). The outer of these is the abdominal wall, the inner the gastrointestinal tract. The external surface of the body is derived from ectoderm and is protective and "relational" in function, while the innermost surface (i.e., the inner lining of the inner tube, which in actual square surface more than equals the area of the skin itself) is derived from endoderm and represents the nutritional tissue of the body. Between these tubes is that

potential space, its walls derived from mesoderm, which is variously known as the abdominal portion of the body cavity, the adult celomic cavity, the extravisceral cavity,

or the peritoneal cavity. The study of these arrangements and of the clinical significance of the three primary germ layers, involves a consideration of four topics:

1. Origin of the gastrointestinal tract.
2. Origin of the peritoneal cavity.
3. Distribution of the adult gastrointestinal tract.
4. Final attachments of the gastrointestinal tract.

In reviewing the peculiar manner in which viscera and body walls are connected, the operating surgeon is chiefly interested in vascular and peritoneal or membranous connections; while for the surgical diagnostician the dominant interest is in nerve connections.

I. ORIGIN OF THE GASTROINTESTINAL TRACT. It will be recalled that the enteric canal (inner lining of the gastrointestinal tract) develops from the yolk sac.¹²¹ It is formed from this structure as the embryonic streak or rudiment bends forward at its cephalic and caudal extremities while creating the anterior abdominal wall (Fig. 89 B). At first the enteric canal is blind at its cephalic and caudal ends while the middle part of its ventral wall is continuous with the wall of the yolk sac (endodermal lining) into which the archenteron (G. first or primitive intestine) is open for about one-third of its length (Fig. 89 C). The portion of the tract thus open into the yolk sac is termed the midgut; that cephalad to this opening, the foregut; and that caudad, the hindgut. The opening into the yolk sac gradually narrows as the anterior abdominal walls close in, but the archenteron retains a connection with the diminishing yolk sac (now a mere yolk vesicle) by a slender tube of smaller and smaller caliber, the yolk stalk, or vitello-intestinal duct (vitelline, L. yolk) (Fig. 89 D). With the degeneration of the yolk sac into a yolk vesicle this vitello-intestinal duct exerts a traction upon the intestine at its point of attachment and thus draws a loop of small bowel out of the body cavity into the umbilical cord. This intestinal loop, with the duct at its apex, consists of two limbs (Fig. 89 E). The first of these has been variously termed the proximal, descending, leaving or efferent limb; the second is known as the distal, ascending, returning or afferent limb. This protrusion of bowel into umbilical cord is known as the "embryonal umbilical herniation." The loop begins to enter the cord in the 10 mm. embryo (three weeks) and the degree of herniation increases until the tenth week of intrauterine life. Normally after this period the bowel returns to the abdomen (explained below). The umbilicus is the last point in the abdominal walls to close and the navel or omphalos represents the central point of the anterior body wall (navel, L. center; *omphalos*, G. a central object). In the adult the only trace of the early connection between intestinal canal and

FIG. 89. Formation of gastrointestinal tract.

B. As the embryo bends forward at its cephalic (1') and caudal extremities (1) the yolk sac becomes constricted and the first evidence of an alimentary canal (embryonic endoderm) appears.

umbilicus is the rare (2 per cent) persistence of a diverticulum or rudiment of a diverticulum, uniting the lower portion of the ileum with the navel (Meckel's diverticulum occurs more or less distinctly in one person in fifty). The visualization of the origin of the enteric canal is aided through the use of accompanying figures.

This brief statement of developmental facts concerns matters which have considerable practical significance. Mention has previously been made of such clinical points as the occurrence of fistulae, cysts and endodermal neoplasms at the navel, the explanation of which depends upon an understanding of the origin of the enteric canal; the persistence at birth within the umbilical cord of a loop of bowel, necessitating care to strip the cord backward to the body wall between the thumb and forefingers before applying clamps or ligatures, has been taken up; the incidence of congenital umbilical hernias has been mentioned, together with the fact that their spontaneous cure within the first two years of life is the rule, due to the inward traction of the umbilical ligaments (obliterated urachus; obliterated hypogastric arteries).

Abnormalities at
the Navel

Diverticula due to the complete or partial persistence of the omphaloenteric or vitelline duct vary widely as to their point of origin from bowel, their site of attachment within the peritoneal cavity, and as to size and shape. It is very often stated that a Meckel's diverticulum, if present, will be found "within 12 to 14 inches of the ileocecal valve,"^{122,123} but the point of origin as a rule is at a considerably greater distance

from the large bowel. Meckel himself simply gave the place of origin as "in the small intestine and nearer its lower than its upper extremity"¹²⁴; he stated that it "varies to a considerable extent." Huntington found by actual measurement in 22 instances of this anomaly that the average point of attachment to bowel was located 107 cm. or 3 ft. 6 in. from the ileocecal valve.¹²⁵ The obvious practical significance of this fact is that when operating for intestinal obstruction of unknown cause, search for a congenital diverticulum of the ileum as a possible cause, should extend over a wider area than the terminal $1\frac{1}{2}$ feet of ileum. At least the terminal $3\frac{1}{2}$ feet of ileum must be examined to discover the average case and the presence of a diverticulum cannot be positively ruled out unless over 9 ft. of terminal ileum are inspected.

A Description of
the Diverticulum
of Meckel

A Meckel's diverticulum is always single. The diverticulum arises from the free margin of bowel (at a point opposite to the mesenteric attachment) and usually passes away from the ileum at a complete or right angle (Fig. 90 A). This congenital anomaly contains all of the coats of the bowel wall, a circumstance which serves to distinguish it from false or acquired diverticula. The diverticulum at its point of origin may have a caliber equal to that of the ileum itself, or it may be smaller, even being a cord with the finest of central apertures (Fig. 90 B). A Meckel's process is always broader at its point of origin than at any other point. It frequently tapers rapidly as it leaves the ileum, although the extreme tip may be somewhat clubbed or bulbous, due to a herniation of the mucus through the muscular coat (Fig. 90 C). At times the diverticulum is a mere pouch or nipple-like process in the lower portion of the ileum. The diverticulum may extend directly to the umbilicus, usually as a cord but rarely as an open duct; it may attach internally to the midline at a varying distance from the umbilicus; at times its extremity is attached to intra-abdominal structures, notably the mesentery of the bowel or the bowel wall (Fig. 90 D); in still other instances, and quite commonly the terminal extremity of the diverticulum

FIG. 90. Varieties of Meckel's diverticulum.

A. Diverticulum leaves bowel at free border (opposite mesenteric attachment) at right angles to long axis of bowel.

B. At times the process is little more than a fibrous cord.

C. The diverticulum is always largest at its point of origin from bowel, but sometimes has a bulbous tip.

D. Tip of diverticulum has acquired a secondary attachment (in this case to broad ligament).

E. Showing vessels (these are called vitello-mesenteric vessels) which may accompany the diverticulum. Note how the vessels pass over and may constrict bowel wall.

F. Diverticulum passing to umbilicus; small endodermal cyst at anterior abdominal wall.

lies free and unattached within the peritoneal cavity, the process having an average length of 3 inches.

Persistent Omphalo-mesenteric Vessels

Vessels may accompany the diverticle, whatever its course. These may consist of an artery and two veins.¹²⁴ They arise from branches of the superior mesenteric vessels, cross over the ileum opposite their points of origin, and traverse the walls of the congenital pouch (Fig. 90 E). These vessels may themselves constrict the bowel. They originally had the function of nourishing the yolk sac and are therefore called the omphalo-mesenteric vessels. In the rarest of instances the arteries or fibrous cords representing them may pass from their mesenteric origin to the region of the umbilicus even when there is no congenital diverticulum of the bowel.

Comparison of True with False Diverticula of the Ileum

In contrast to the diverticulum above described, acquired or false diverticula of the ileum are almost without exception multiple.¹²⁶ They arise along the attachment of the mesentery to bowel wall, not at the free bowel border (Fig. 91). They are short; they are polypoid or clubbed, and at their point of origin are narrower than at other parts. Although subject to secondary inflammation they do not cause mechanical obstruction of bowel. They occur in old people, rarely in the young. These multiple acquired outgrowths are caused by protrusion or herniation of mucous lining through the muscle coat; they never, as does a Meckel's diverticulum, contain a covering of muscle. False diverticula, then, differ from a Meckel's process in all essential points, in structure, number, shape, position, size, age incidence and potentialities:

The omphaloenteric duct or persistent omphalo-mesenteric vessels give rise to intestinal obstruction in 4 ways: (1) by bowel strangulation under a fibrous cord or diverticulum; (2) by loops or nooses of the diverticulum or a cord; (3) by those remarkable formations known as diverticular knots, and (4) by the passage of the diverticulum into a hernial sac (Fig. 92).

The first method is by far the most common (outnumbers the other causes by over three to one). Obstruction rarely occurs when the attachment of the diverticulum is to the

FIG. 91. Differentiating a congenital diverticulum (Meckel's) from acquired or false diverticula. The former is single, contains all coats of bowel, arises at free border of bowel, has its largest caliber at its point of origin and is 3 inches in length. The false diverticula are multiple, short, pedunculated, contain no muscular coats, and arise along the attachment of the mesentery to bowel, not opposite to free bowel margin. (From 3rd Surg. Div., Bellevue Hosp.)

FIG. 92. Intestinal obstruction from congenital diverticula (Meckel's).
 1. Obstruction beneath diverticular band. 2. Obstruction by a diverticular noose. 3. Obstruction by a diverticular knot. 4. Obstruction of diverticulum within a hernial sac. 5. Obstruction from angulation of ileal loop by diverticular traction.

umbilical region, but commonly occurs when there is a secondary attachment to mesentery or bowel. These points of secondary attachment are often determined by intraperitoneal inflammations and have been reported at the site of old inguinal hernias, sclerotic mesenteric glands, or to inflammations about ovaries, tubes or appendices. When the diverticulum is short only a small knuckle of bowel is capable of engaging beneath the resultant loop, but when the loop is long a large portion of bowel may become either incarcerated or strangulated. The diverticulum sometimes forms a loop or a compound loop into which bowel becomes engaged and subsequently ensnared as a later change occurs in the lines of traction within the belly. Intestinal obstruction from knots is explained graphically in accompanying figures. A bulbous enlargement of the tip of the diverticulum, as previously referred to, plays an important rôle in the formation of these peculiar knots, for once the knob-like process has become engaged through an aperture it does not again readily become disengaged.

Varieties of Intestinal Obstruction from Persistent Omphalo-enteric Ducts

The study of embryology aids not only in an understanding of diverticula but also in the interpretation of symptoms produced by gastrointestinal disorders. It proves particularly valuable in explaining the localization of pains due to alimentary tract affections. The six-weeks' embryo with its primary loop of bowel and its simple distribution to this loop of vessels and nerves, furnishes a picture which makes readily intelligible the distribution of such pains to the midline of the anterior abdominal wall. To determine the exact sites to which the patient refers his pains is a matter of the utmost importance in the diagnosis of surgical disorders within digestive organs. As early as 1892 MacKenzie published results of a careful inquiry into this pain-reference as described by 320 patients suffering from affections of stomach.¹²⁷ He found the pain in 95 per cent of cases to be localized within the epigastrium. Subsequently, after keeping records of several thousands of cases, he reached the conclusion that the patient does not

Site of Pain From Gastro-intestinal Affections

FIG. 93. I. The shaded parts show the areas in which pain is felt in affections of the digestive tube. (From Mackenzie.)

A. Area in which pain is felt in affections of the esophagus. B. Area in which pain is felt in affections of the stomach. C. Area in which pain is felt in affections of the small intestine. D. Area in which pain is felt in affections of the large intestine.

II. The shaded area shows site of pain, x corresponds to the position of the ulcer in the stomach as found at the post-mortem examination.

III. The shaded area shows the site of pain, and the position of the gastric ulcer as found at operation.

IV. The shaded area shows the site of pain, x the site occupied by the ulcer at the pyloric orifice of the stomach as found at the post-mortem examination.

actually feel pain within the viscera themselves but refers it to the abdominal walls and to the area of distribution of sensory nerves of the cerebrospinal system. And according to the observations of Mackenzie the pain from digestive disturbances is interpreted by the patient as arising at the periphery of this sensory nerve distribution, that is, approximately at the midline of the body anteriorly. He stated "from the top of the oesophagus to the anus there is, in the vast majority of cases, a limitation of the distribution of the pain to an area extending down the centre of the body from the middle of the sternum to the symphysis pubes."¹²⁷ (Fig. 93.) Thus, when the inner lining of the oesophagus is irritated by a too hot drink, pain is always referred to a region over the lower part of the sternum; organic lesions of stomach, whether located near cardia or pylorus, give rise to pain which is referred to the epigastrium; such conditions of small bowel as strangulation of an intestinal loop yield pain which is felt in the neighborhood of the umbilicus; and again, affections of large bowel (volvulus of sigmoid, diverticulitis, stricture) when these cause pain, cause it within the hypogastrium.

There are several ways of demonstrating that the pain is not actually felt "within" esophagus, stomach, or bowel or "inside of the belly" as the patient may himself believe and state. The following facts well illustrate the reference of the pain to the tissues of the body walls; gastric pain is epigastric in location although the stomach itself may lie at a lower level or even extend into the hypogastrium or pelvis and the epigastric pain remains constant in location although the stomach is known to shift about during periods of functional activity. Again, while the intestinal loops twist and coil throughout the entire infracolic division of the abdominal cavity and are quite largely hypogastric and pelvic in location, small bowel pain without accompanying peritonitis is referred with uniformity to the area about the umbilicus.

Mackenzie's original illustration of the areas in which pain is felt in affections of the digestive tube is reproduced in

Pain Reference to
the Periphery

The Three Equi-
distant Pain Zones
of the Midline

Figure 93. Considering the anatomical distribution of the various components of the gastrointestinal tract, the nature of this reference of pain to the midline of the body is astonish-

FIG. 94. Study of reference of gastrointestinal tract pains to three equidistant zones in midline of anterior abdominal wall.

ing. Why does it occur that affections of stomach and duodenum give rise to pain which is felt over some 6 in. of the midline while affections of small intestine, within any part of its many feet of tortuous course, have a body-wall zone of no greater size (the 5 or 6 in. about the umbilicus)? What accounts for this inequality of length between the areas of pain-reference and of the bowel divisions themselves? Why is it, also, that large bowel pain is situated at a lower point than small bowel pain, when anatomically the colon describes a loop about the periphery of the abdomen and has right and left flexures which reach to the hypochondriac regions, while the terminal ileum is situated at such a low point in the abdomen or even within pelvis? It is when the adult surface map for pain is juxtaposed to a picture of the six-weeks' embryo that the situation becomes easily clarified (Fig. 94). It may be noted that the upper third of the abdominal portion of the archenteron gives rise to the stomach and proximal duodenum;

that the mid-third gives rise to terminal duodenum, all remaining parts of small intestine, to cecum, appendix, ascending colon, and to the proximal portion of the transverse colon; that the distal third of the primitive bowel gives rise to the remainder of the colon. Since the nerve tissue is being distributed at this period of development (see invasion of ectodermal tissue into the abdominal cavity) and since the central nervous connections are established at this time, it follows that all subsequent twists, elongations or other changes occurring in individual portions of the tract have but little effect upon adult reflex pathways. The relationships of the three primary divisions of the archenteron to the three equi-distant zones of the midline of the anterior abdominal wall remain fixed and constant.

But while stomach disorders produce, with great regularity, pain which is epigastric in situation, it by no means follows that epigastric distress always signifies some gastric lesion. The stomach has been referred to as "the spokesman of the abdomen"¹²⁸ and roughly only about one-third of stomach symptoms are due to actual gastric lesions. Another third are caused by extragastric diseases existing within the abdomen or pelvis, as for example cholelithiasis, chronic appendicitis, tuberculous peritonitis, ovarian cyst, salpingitis. The remaining third of gastric symptoms are due to conditions not even located within the abdomen but existing entirely outside of this cavity as, a basilar meningitis, brain tumor, pulmonary tuberculosis, or exostosis associated with a lower thoracic vertebra. (The mechanisms by which these facts are explainable are discussed elsewhere.) Lesions at almost any point in the body may cause gastric symptoms through a direct or indirect involvement of gastric vessels and nerves. A list of such conditions, would necessarily be long and include general headings as endocrine disturbances, psychic disturbances, drug poisonings, abdominal allergies, etc. The ability of the diagnostician to arrive at a correct diagnosis will be limited unless he is thoroughly familiar with the many medical and surgical

Gastric Lesions vs.
Epigastric Distress

conditions represented by the extensive list of actual causes. Given a patient, then, complaining of gastric symptoms, a complete study of all phases of the case is an obvious necessity

FIG. 95. The duct system of the liver arises as an outgrowth of the developing duodenum. (From Waterston. Cunningham's Anatomy.)

in arriving at a correct diagnosis. This means not only a thorough examination of all parts of the abdomen and pelvis but also of head, neck, thorax, extremities and of every region of the body; it involves not only a careful history but adequate laboratory tests as well. The abdominal spokesman simply tells of the presence of trouble; it remains for the diagnostician to definitely identify the organ or tissues diseased.

Chronic Dyspepsia and Gall Bladder Disease

There are, nevertheless, certain clinical rules and guides in dealing with epigastric distress which may be relied upon to a considerable extent as indicating, at the first examination of the patient, the true diagnosis. Perhaps the most common extragastric cause for epigastric distress is some affection of the biliary adnexa. The possibility of gallstone disease should always be borne in mind in any case of chronic indigestion. The bile ducts (endodermal portion) arise as an outgrowth of the developing duodenum (Fig. 95) and it might therefore be anticipated that if they produce, as do remaining portions

of the enteral tube, a reference of pain to the midline of the anterior abdominal wall, the site of this referred pain would either be some region between the surface zones for gastric and small intestinal pain or would coincide with that for duodenum. In other words, there are theoretical reasons why the pain with biliary tract disorders should be felt within the epigastrium. And the study of clinical records shows that in 20 to 40 per cent of cases of cholelithiasis and cholecystitis the site of pain is solely within the epigastrium.^{129,130} In addition, when the chief complaint is right hypochondriac pain there is almost always some epigastric pain as well. There are reasons to believe that, regardless of its final radiations or other localizations, biliary duct pain (visceral pain unassociated with local peritonitis, adhesions, or other complications) is primarily epigastric. How often are unsuspected diseases of the gall bladder discovered during laparotomies? The fact that the anatomical area overlying the gall bladder itself is often not directly indicated by the symptoms is borne out by the considerable percentage of instances in which gallstones are clinically characterized as "silent." The records of these cases carry such statements as the following: "there were no preoperative symptoms referable to the gall bladder," "the complaints before operation were entirely gastric." In the absence of a typical biliary colic a diagnosis of "dyspepsia," "atonic gastritis," "chronic indigestion," is made with great frequency. Often it is only when a true "biliary colic" has occurred, with its right upper quadrant tenderness and rigidity and with the associated pain to the right shoulder, inspiratory dyspnea, and possibly jaundice, that attention is finally directed to the stone which for months or years had been causing varying degrees of epigastric discomfort or even, with the ingestion of fried, fat or greasy foods, of real epigastric pain. The so-called gastric symptoms of biliary tract disease are usually said to be due to a "reflex stomach" (viscero-visceral or vagus reflexes) and such gastric dysfunctions as hypermotility, hyperirritability, hypersecretion and pyloro-

spasm, may be demonstrated by fluoroscopic examination or the analysis of gastric contents; yet there seems clear evidence that in addition, or perhaps of even more importance

FIG. 96. Tubular structures often giving rise to colicky abdominal pains. (After Cope.)

1. Gall bladder and biliary ducts. 2. Right ureter. 3. Appendix. 4. Right fallopian tube. 5. Pancreatic ducts. 6. Loop of small bowel. 7. Left ureter. 8. Left fallopian tube.

in the production of epigastric distress, the gall bladder itself, without any reference to stomach dysfunctions, is capable of initiating epigastric pain.

The Nature of Colics

Colics occur almost exclusively in muscular tubes or in ducts of small caliber (Fig. 96), as biliary ducts, ureters, loops of small intestine, the characteristic intense intermittent pain being associated with strong peristaltic waves or smooth muscle spasms. Increases in intraluminary tension seem to be

an important factor in the causation of the typical colics. Since the stomach is a hollow muscular organ it might be anticipated that this organ would be the cause of pain of a cramp-like or colicky nature. Yet the typical gastric pain is not of this type and true colics from stomach affections are of rare occurrence. In his study of epigastric pain Mackenzie has gone so far as to state, "it will usually be found in the long run, that the so-called 'cramp in the stomach' in which there is pain of great severity referred to the epigastrium is due to gallstone colic. I have watched many patients for years who suffered from these severe attacks, and found that they *all* turned out to be cases of gallstone colic."¹²⁷ Colicky pain in the epigastrium, then, constitutes presumptive evidence of the presence of gallstones.

In those rare instances in which the stomach itself does undergo a sufficiently violent and massive contraction to cause pain of a colicky nature the resulting pain is not difficult to differentiate from the colics (right hypochondriac or epigastric) of biliary tract diseases. For when the stomach contracts as a whole there is implication of the cardiac as well as of the pyloric end of the organ and this causes pain which extends upward well over the sternum and to areas supplied by the fifth or even the fourth thoracic nerves. This pain not infrequently is associated with the regurgitation of acid gastric contents into the lower end of the esophagus and with the symptoms of pyrosis or heartburn. Because of the height to which it extends such pain has been mistaken for that of angina pectoris. Although the pain reference may be over the area of the heart the condition is but a pseudoangina for it is not related in any way to actual cardiac disease; pain, tenderness and hyperesthesia, such as extends into the arm with true angina, serve to distinguish the diseases and a complete study of the circulatory system combined with a good history should leave but little doubt as to the final diagnosis.

The characteristic pain of stomach lesions, particularly of ulcers, is dull, boring and deep-seated. It does not have either

Gastric Pain Simulating Angina Pectoris

The Pain of Peptic
Ulcer

the intensity nor the spasmodic nature of a colic. In most instances it has a certain periodicity and its outstanding feature is a relation to the intake of food. While the time of onset of the pain after eating varies in individual cases, with the single case there tends to be an almost "clock-like" regularity in the onset of the discomfort after the taking of food.¹³¹ A young individual who is hungry but afraid to eat because eating regularly sets up pain almost surely has a peptic ulcer. Ulcer distress is a quantitative dyspepsia rather than a qualitative dyspepsia as is seen with gall bladder diseases. The character of the food makes little difference; it is the fact that something is placed in the stomach which causes the distress; when the ulcer pain is severe even very small amounts of food uniformly initiate the symptom. The time of onset of pain bears a rough relationship to the distance of ulceration along the digestive tract. It has been stated that pain occurring immediately, or within a half-hour after eating, indicates ulceration near the esophagus, while that beginning from half-an-hour to an hour-and-a-half after the ingestion of the meal is probably indicative of a prepyloric lesion; and that when the postcibal pain is still later in onset the ulcer is likely to be duodenal.

Cycles or Rhythms
with Peptic Ulcer
Pains

This relationship to food has been termed "cyclic" in nature and Moynihan has spoken of a "rhythmicity" with peptic ulcer pain.¹³² The rhythm with duodenal ulceration is triple and with gastric ulceration is quadruple. With duodenal ulceration the cycle is: food-relief-pain, food-relief-pain (a triple rhythm), for the discomfort begins so long after the ingestion of food as to be termed a "hunger-pain" and following the intake of food or alkalies there is a long period of relief. With gastric ulcer the rhythm is: food-relief-pain-relief; food-relief-pain-relief (a quadruple rhythm) for the pain wears off gradually before time has arrived for the ensuing meal and the period of relief after eating is so brief that the patient fears the effect from putting anything into the stomach.

These few clinical points relative to epigastric pains and to body-wall pains from gastrointestinal tract affections in

the Digestive Tract

general have, perhaps, been rendered somewhat more readily understandable through the study of the development of the alimentary tube. A consideration of similar clinical rules regarding umbilical and hypogastric pains will be deferred in order that still other embryological arrangements, important in explaining everyday surgical matters, may first be investigated. A detailed review of the innervation of the gastrointestinal tract is reserved for a separate section (visceral neurology) where specific nerve connections and individual reflex pathways may be dealt with. Such additional study will make apparent that the reference of enteral pains to the tissues of the midline of the body wall takes place by way of the splanchnic nerves (sympathetic nervous system). The production of additional disturbances within the tissues of the body surface by way of the vagus nerves (autonomic fibers) will later be considered (reflex phenomena of scalp, temples, face, jaws, neck). The briefest summary of the nerve supply of the gastrointestinal tract might be stated as follows:

a. A supply from the sympathetic system (splanchnic nerves) to stomach, small intestine and the greatest part of the great intestine.

b. A supply from the bulbar autonomic system (vagus nerves) to the tract walls from the mouth to the descending colon.

c. A supply from the sacral autonomic (nervus erigens or pelvic vagus) to the descending colon and rectum.

d. A supply to the extreme cranial and caudal ends of the tract (derivatives of stomatodeum and proctodeum) from the cerebrospinal nervous system (Fig. 97).

EPONYM

JAMES BENIGNUS WINSLOW*

Foramen of Winslow. Foramen epiploicum; a small orifice of communication between the greater peritoneal cavity and the omental bursa (lesser peritoneal cavity; Winslow's pouch).

Odeuse, Denmark, April 2, 1669.

April 3, 1760, aged ninety-one.

First studied theology in native land.

1697: Pre-medical studies in Holland.

1698: Continued studies in Paris.

Student of famous French anatomist Duverney who encouraged his natural inclination toward anatomy.

1702: Matriculated in University of Paris.

1703: Delivered thesis dedicated to Bossuet (French writer and orator) who, being ill, had himself carried to the university to hear the presentation.

1705: Degree, Doctor of Medicine, University of Paris.

1707: Presented to Royal Academy of Sciences by Duverney. Duverney had such confidence in his pupil that he often entrusted him with his lectures on Anatomy and Surgery at the Jardin du Roi. After the death of Duverney the chair at Royal Garden fell to Hunault, but later to Winslow. Winslow continued to fulfil this assignment as long as age permitted.

Eponymic not only with reference to the foramen epiploicum but also for Winslow's ligament (a fasciculus forming part of the posterior ligament of the knee joint ligamentum popliteum obliquum running from the tendon of the semimembranosus to the back part of the outer condyle of the femur) and for Winslow's stars (capillary whorls in the lamina choriocapillaris from which arise the venae vorticosae). Winslow did much to systematize the anatomical knowledge of his time, particularly in reference to myology.

Among his published books and papers were:

1711: Observations sur les fibres du coeur et sur les valvules, avec la manière de la préparer pour le démontrer. *Mem. de l'acad. d. Sc.*

1715: Nouvelles observations anatomiques sur la situation et la conformation de plusieurs visceres. *Mem. de l'acad. d. Sc.*

1717: Description d'une valvule singuliere de la veine cave, et nouveau sentiment sur la fameuse Question du trou ovale.

1729: Observations anatomiques sur la rotation, la pronation, la supination, et d'autres mouvements en rond.

1732: Exposition anatomique de la structure du corps humain. Paris, also English, German and Italian versions.

1742: Dissertation sur l'incertitude des signes de la mort. Paris.

Exposition anatomique de la structure du corps humain, Paris, 1732, 2: 170, 352-365.

Winslow tested the communications of the foramen bearing his name by the ingenious method of inserting into this opening a quill or pipe, well fitted to the orifice, and then after blowing through the quill, observing the course and distribution of the air. He found that air distended the greater omentum, filling it like a bladder or balloon.

The surgeon seldom thinks of the great omentum as being "a bladder" and only sees the potential space within the omentum filled when, for example, loops of small bowel have passed through the foramen epiploicum (hernia through foramen of Winslow) or when blood or gastric contents occupy the cavity after injury to or perforation of

VOL. II.

The FIFTH EDITION, corrected.

B

DEDICATION.

T O

Dr. JAMES DOUGLAS.

S I R,

WHAT I here take the Liberty to offer You, is already more Your own than mine. To You I owe all that I know, not only of the Science, but of the Style of Anatomy; and there is not one good Line in this Translation, which is not the better for what You have taught Me, or procured Me Opportunities of learning. These are very great Obligations to a Man resolved to live by the Profession of Physick; but they are very small, when compared with others that You have laid Me under, without which I should never have been in a Condition to live by any Profession. Pardon this publick Acknowledgment of Favours which You designed to have kept always secret; and continue to believe Me with the utmost Sincerity, Gratitude and Respect,

S I R,

Your Most Dutiful,

Bow-Lane,
Sept. 5, 1732.

Most Obliged Brother,

G. DOUGLAS.

Fig. 99. Unusual dedication to English edition of Winslow's work, in which G. Douglas pay a beautiful tribute to his brother James Douglas.

*Structure,
Uses, and
Coverings of
the Omentum.*

352. THE Omentum is a large, thin, and fine membranous Bag, furrowed on all Sides by numerous Portions of Fat, which accompany and even invest the same Number of Arteries and Veins adhering closely to each other.

353. The greatest Part of it resembles a Kind of flat Furle, or a Sportsman's empty Pouch, and is spread more or less on all the small Intestines from the Stomach to the lower Part of the Regio Umbilicalis. Sometimes it goes down to the lower Part of the Hypogastrium, and sometimes it does not reach beyond the Regio Epigastrica. It is commonly plaited or folded in several Places, especially between the Portals of the Liver.

354. It is divided into two Parts, a right and a left, and a right and a left Side of the Stomach. The right Side is fixed to the common Ligament or Auneon of the Duodenum and Colon, and to the contiguous Parts of these two Intestines. That on the left Side is fixed to the longitudinal Scissure of the Spleen, to the Extremity of the Pancreas, and to the convex Side of the great Extremity of the Stomach. It is likewise fixed to the membranous Ligament, which sustains the Ductus Cholidochus, and connects it to the Vena Portæ Ventralis.

355. Below these Adhesions the other Portions, that is, the anterior, posterior, two lateral and inferior Portions, which last is the Bottom of the Sacculus Epiploicus, have commonly no fixed Connexions, but lie loose between the Portals of the Liver, and the great Extremity of the Stomach.

356. The Membrane of the Omentum, if it were of a simple texture or some compound Membrane, it would be more convenient to call them Folia, Alæ, or some such Name.

357. The Omentum is composed of two Laminae, with a Mixture of the same Portions of Fat, which are considerably finer than the other.

358. The little Omentum is thinner and more transparent than the other, and its Cavity communicating with all the great Vessels of the Liver, and the prominent Portion of the Lobulus.

359. We may satisfy ourselves concerning these Continuities, by making a small Hole in one of the Laminae of the Omentum near the Stomach, Colon, &c. and by blowing into that Hole, through a Pipe well fitted to it; for the Air will gradually insinuate itself under the common Coats of these Viscera: But if the Parts be dry, they must be moistened a little, before the Experiment is made.

359. We see from this Situation of the two Omenta, that in the Space left between the lower Side of the Stomach and upper Side of the Mesocolon, they have a very broad Communication with each other, so that if either of them contained in its Cavity any Fluid, that Fluid might readily get between the Stomach and Mesocolon, and so pass into the other Bag, especially when the Stomach is empty and consequently its Situation easily changed.

360. THEREFORE by Means of this Interspace between the Stomach and Mesocolon, the two Omenta form one Cavity, which opens into the Cavity of the Abdomen by one common Orifice, situated near the Commissure on the right Side of the great Omentum. This Orifice is femilunar or semicircular, and formed by the Union of two membranous Ligaments.

361. To discover this Orifice of the Omentum, we need only raise a little the great Lobe of the Liver, and find out the Root of the Lobulus, and apply to it a large Pipe wrapt round with Cotton, Wool, or Tow, to hinder the Regress of the Air. Then if we blow gradually, the Air will inflate the Sides of the great Omentum, and give it the Appearance of a large Bladder.

362. When we touch these Membranes with dry Fingers, they stick to them so closely as hardly to be separated without being torn, as we see by the reticular Holes which appear in those Portions of the Membranes that have been thus handled. In that Case it is to no Purpose, to blow through the natural Orifice already mentioned; and it is owing to these small Holes that the Membranes of the Omentum have been supposed to be naturally reticular.

363. The membranous Laminae of the little Omentum are contiguous partly with the external Membrane of the Liver, partly with that of the Stomach, and a little with the Membrane that lines the neighbouring Portion of the Diaphragm. Those of the great Omentum are continued partly with the same Coat of the Stomach, and partly with the external Covering of the Colon, and consequently with the Mesocolon; and they likewise communicate with the Covering of the Spleen.

364. We may satisfy ourselves concerning these Continuities, by making a small Hole in one of the Laminae of the Omentum near the Stomach, Colon, &c. and by blowing into that Hole, through a Pipe well fitted to it; for the Air will gradually insinuate itself under the common Coats of these Viscera: But if the Parts be dry, they must be moistened a little, before the Experiment is made.

365. We may satisfy ourselves concerning these Continuities, by making a small Hole in one of the Laminae of the Omentum near the Stomach, Colon, &c. and by blowing into that Hole, through a Pipe well fitted to it; for the Air will gradually insinuate itself under the common Coats of these Viscera: But if the Parts be dry, they must be moistened a little, before the Experiment is made.

366. We may satisfy ourselves concerning these Continuities, by making a small Hole in one of the Laminae of the Omentum near the Stomach, Colon, &c. and by blowing into that Hole, through a Pipe well fitted to it; for the Air will gradually insinuate itself under the common Coats of these Viscera: But if the Parts be dry, they must be moistened a little, before the Experiment is made.

FIG. 100. Facsimile of English translation of words of Winslow relative to the foramen epiploicum.

the posterior wall of the stomach. At other times the great omentum resembles a caul or great apron overlying the small intestinal loops (flat). Winslow's observations in regard to distention of the great omentum by air may be verified, however, providing the experimenter moisten his fingers in oil as directed, when handling the parts.

Study of the original words of Winslow is rendered difficult for the modern student by reason of the fact that Winslow uses the term "lesser omentum" in a different sense from that in which it is now employed. The "lesser omentum" of this author corresponds to the omental bursa (lesser peritoneal cavity) of the present. When Winslow's writings are reviewed, substituting "omental bursa" for "lesser omentum," the descriptions become more readily intelligible.

Winslow seems to have been the first to employ the term omentum in its present sense. He describes the cavity of the great omentum as resembling a "sportsman's purse or bag"; and much might be said in favor of his method for describing the omental bursa, and for terming this space and its peritoneal coats a "lesser omentum." Thus a hand introduced through an opening in the gastrocolic or great omentum lies within the large "sportsman's pouch" whereas a hand introduced into an opening in the present lesser omentum (above the stomach) (through the gastrohepatic omentum) would lie in the smaller "sportsman's pouch." These two "pouches" would be found to communicate with each other, as described, and to open in common through the foramen epiploicum into the general or greater peritoneal cavity.

Although the photostat of the English Translation of Winslow's "Exposition Anatomique" shows the first name James, dictionaries and medical histories variably use the first names James, Jacob, and Jacobus.

In beginning his medical studies Winslow was granted financial aid or "a pension" by the government of Denmark, in order "that the country might not be without participation in the glory of advancing the progress of anatomical knowledge." Later he received financial aid from the Bishop of Meaux. The Bishop died in 1704 (one year prior to Winslow's graduation). Deprived of aid Winslow addressed himself to the faculty of the University of Paris "which was not deaf to his pleas but even paid all his expenses for the rest of his course."

Winslow's father and grandfather were Lutheran pastors and Winslow first studied for the ministry. He then turned to the study of medicine and finally forswore the religion of his fathers to turn Catholic. He was, therefore, disinherited by his family.

It has been written that Winslow's exposition on the structure of the human body was the "first treatise of descriptive anatomy divested of hypothetical physiological details and explanations foreign to the subject" and that his work represented a "close description derived from actual objects rather than from reference to the writings of previous anatomists."

QUESTIONNAIRE

1. What is the mechanical effect of the loss of abdominal fat?
2. Name some of the functions of intra-abdominal fat.
3. Why does it often prove so difficult to reduce a large umbilical or ventral hernia?
4. What special preoperative care is advisable in treating fat patients who have large ventral hernias?

5. What is meant by static pressure?
6. Explain some of the interrelationships between intravisceral, intraperitoneal and static pressures.
7. Discuss the effects of gravity in regard to the Fowler position, the Trendelenburg position, the knee-chest position.
8. What is meant by the cushion effect of air-containing organs?
9. What is the effect of an increase in the pressure exerted upon an organ containing fluid; one containing gas?
10. Explain the effects of gravity upon hernial masses.
11. Why do organs herniate both downward through the inguinal rings and upward through the diaphragm?
12. What is meant by garrulity of the vulva? Give the mechanism by which this phenomenon is produced.
13. What is the value of the knee-chest position?
14. State the instructions to be given to a woman who is to take the knee-chest exercise.
15. What is the habitus enteropticus?
16. What is visceroptosis?
17. What is the intra-abdominal condition found to be present with a congenital visceroptosis?
18. Why do patients with visceroptosis have sharp intercostal angles?
19. What are the chief symptoms of visceroptosis? Their cause?
20. State some of the methods for replacing and retaining in position prolapsed abdominal viscera.
21. What are some of the causes of acquired visceroptosis?
22. What are the chief differences as to symptoms and treatment between congenital and acquired visceroptosis?
23. What is the usual effect of pregnancy upon the symptoms of visceroptosis?
24. Give the technic of one or more methods for supporting the abdomen by means of adhesive dressings in the treatment of visceroptosis.
25. What requirements must be fulfilled by an abdominal belt as used in the treatment of visceroptosis?
26. What exercises are of particular value in the treatment of visceroptosis? How do these act to prove the condition of the patient?
27. Give a list of from 5 to 10 factors which have an important bearing upon pressure conditions within the abdomen.
28. Is the peritoneal cavity an actual or a potential space?
29. What effect has opening the peritoneal cavity upon the tensions between the various abdominal viscera and between the viscera and the abdominal walls?
30. When is it correct to use the term intra-abdominal pressure? What are the objections to the term?
31. Of what importance is it in instituting treatment to correctly interpret among the many forces active, the actual cause or causes of any abnormal pressure conditions within the abdomen?
32. What is the length of the alimentary canal? What factors seem to necessitate this extreme length?
33. What is the derivation of the following terms; intestine, alimentation, digestion?
34. From what primary germ layers are the following tissues derived; inner lining of enteric canal, skin, peritoneum, nerves of intestinal tract, muscles of intestinal walls?
35. What is meant by the following terms; yolk sac, yolk vesicle, vitelline duct, omphalomesenteric canal, omphalomesenteric vessels, Meckel's diverticulum, archenteron?

36. What is the primary loop of bowel; name the parts of this loop. What is the foregut, hindgut, midgut?
37. Why does a loop of gut protrude into the umbilical cord in early embryonic life?
38. Explain with sketches the embryological development of the gastrointestinal tract.
39. What is the normal incidence of a persistent omphaloenteric duct?
40. What are the various shapes in which Meckel's diverticula may occur?
41. What is the usual length of a Meckel's diverticulum? What is the average distance from the ileocecal valve for the attachment of the diverticulum to bowel? How much variation is there as to the site of this attachment?
42. What vessels may accompany a Meckel's diverticulum? What are the origin and function of such vessels?
43. In what ways do acquired diverticula of bowel differ from congenital diverticula?
44. Contrast acquired and congenital diverticula on the following points; number, shape, size, position, structure, age incidence, potentialities.
45. What is a false diverticulum?
46. Name several ways in which a Meckel's diverticulum or persistent omphalomesenteric vessels may cause intestinal obstruction.
47. What is a diverticular knot? Sketch some of the more common types of congenital diverticula and the more common intra-abdominal complications they may cause.
48. Why are pains from gastrointestinal affections most often referred to the midline of the anterior abdominal wall?
49. To what areas are pains referred from affections of the following structures; esophagus, duodenum, biliary ducts, ileum, jejunum, cecum, appendix, colon, rectum? Why do these cause pains limited to the areas described?
50. Where is the primary pain of the following conditions most likely to be referred; volvulus of sigmoid colon, herniation of small bowel into fossa of Treitz, gastro-mesenteric ileus, biliary colic, duodenal ulcer, gastric ulcer, acute esophageal dilatation, diaphragmatic pleurisy, appendiceal colic, Deitl's crisis, embolism of superior mesenteric artery?
51. What evidence is there that pains due to visceral affections are referred to skeletal tissues and that the pain is not actually referred to the involved viscus itself?
52. What are the chief zones found by Mackenzie as the sites for referred pains with gastrointestinal affections?
53. What accounts for the inequality between the length of the body wall zones to which pain is referred from various units of the alimentary canal and the length of the bowel divisions themselves?
54. Why is large bowel pain felt at a lower point than small bowel pain when the large bowel reaches to the hypochondriac regions while the small bowel lies in part within the pelvis?
55. At what period in development are nerve pathways in the gastrointestinal tract determined? Do these early central nerve connections change in later life? If so, how?
56. What percentage of gastric symptoms are due to actual gastric lesions?
57. What are the chief extragastric causes of gastric symptoms?
58. What is meant by terming the stomach "the abdominal spokesman?"
59. How do the following conditions cause alterations in gastric motility and secretory activity; brain tumor, basilar meningitis, cholelithiasis, tabes mesenterica, Pott's disease?
60. Along what broad lines are gastric lesions to be differentiated from extragastric conditions causing gastric symptoms?
61. What is meant by "silent gallstones?"

62. What percentage of the distress with cholelithiasis and cholecystitis is epigastric in location?
63. Describe a typical biliary colic. What are the chief associated symptoms?
64. What is meant by a "qualitative dyspepsia;" a "quantitative dyspepsia?"
65. What are the characteristics of a colicky pain? Causes?
66. What is the usual cause of a severe epigastric colic?
67. What is the site of the colicky pain due to a massive or generalized contraction of the stomach?
68. How may gastric affections simulate angina pectoris?
69. What is the typical pain with peptic ulcerations?
70. Explain the relationship between ulcer pain and the ingestion of food.
71. What is meant by a "rhythm" or "cycle" in ulcer pain?
72. What is meant by the "triple rhythm of duodenal ulcer pain" and the "quadruple rhythm of gastric ulcer pain?"
73. By what nerve pathways are pains of gastrointestinal tract origin referred to the forehead, scalp, jaw and neck?
74. Briefly describe or sketch the innervation of the gastrointestinal tract.

SUBJECT INDEX TO VOLUME VIII

(B.B.) = Bookshelf Browsing. (Bi.B.) = Biographical Brevities. (B.R.) = Book Review. (E.) = Editorial

Abscess, amebic, of the liver, 983
 appendicial (walled off), 614
 Abdomen, causation, prevention and treatment of postoperative distention of, 28
 Abdominal surgery, intraperitoneal infusion and autotransfusion in, 1269
 Abortion and contraception (E.), 675, 1310
 Achievements of uterosalpingography, 1245
 Acute appendicitis, treatment of, 759
 dilatation of the stomach, 1194
 infectious diseases (B.R.), 692
 pancreatitis, 1286
 Addison's disease (Bi.B.), 1312
 Adenomatous polyp, rectal, with carcinomatous degeneration, 829
 Adhesions, abdominal, prevention of, 1186
 intra-abdominal postoperative, 1012
 Aids to orthopaedic surgery (B.R.), 691
 Alkalosis, 1218
 Alleged penetration of the human urethra by an Amazonian catfish called Condírú, (B.B.), 170, 443
 Amebic abscess of the liver, 983
 dysentery: its occurrence in routine surgical practice, 54
 American association for the study of goiter (E.), 1311
 illustrated medical dictionary (B.R.), 190
 Anarectal region, minor surgery of, 349
 Anastomosis, resection, and, of the impervious urethra, 1072
 Anatomical variations in the thyroid as a cause of recurrent goiter, 92
 Anatomy, embryology, and surgery of the prostate gland, 526
 Anesthesia, local, reduction of simple fractures of the extremities, under, 1062
 rôle of, in office practice, 340
 rectal, new and efficient, 97
 spinal and shock stretcher, 572
 light specific gravity solutions versus heavy, 773
 complications of, 1165
 Angiofibrolipoma of kidney, 110
 Antiseptics, use and abuse of, 264
 Antra, maxillary, roentgen-ray diagnosis of polypi, 1039
 Apparatus improved, for the air injection of joints,
 Appendicial abscess (walled off), 614
 Appendicitis, mechanical, 1292
 chronic, inquiry into the case for (E.), 887
 clinical and pathological aspects of, 793
 Appendix, inflammation of, its influence on the pelvic organs and the vertebral column (pain in the small of the back, lumbosacral syndrome), 872
 Myxo-globulosis of, 1083
 Applied physiology (B.R.), 1107
 Arthrodesis, extra-articular, of the hip by bone graft, for tuberculosis of the hip, 764
 for flail wrist, 621
 Atlas, simple lateral luxation of, 831

Balanitis, simple, 386
 Benign uterine hemorrhage, radiation therapy for, 1241
 Better protection in vertical fluoroscopy, 859
 Biliary disease, surgical aspects of, 750
 Biographical brevities, 169, 442, 680, 902, 1103, 1312
 Biographisches Lexicon der hervorragenden Ärzte aller Zeiten und Völker (B.R.), 689, 1108

Biology, human, and racial welfare (B.R.), 908
 Biopsy, cervical, office technic of, 346
 Bladder, carcinoma of; ureterosigmoidal implantation, total cystectomy, 1068
 diverticulum complicated by carcinoma of cloacal origin, 627
 Bleeding from the vagina, 295
 Blood and plasma, volume of, in health and disease (B.R.), 690
 picture and its clinical significance (B.R.), 191
 Bodies, foreign, in os calcis, 1071
 Boils, collodian treatment of, and carbuncles, 371
 Book reviews, 188, 189, 190, 191, 688, 908, 1106, 1315
 Bookshelf browsing, 170, 443, 681, 903, 1104, 1313
 Bowel, transplantation of ureter into, 620
 Brain, foreign bodies in, 819
 injuries, dangers of hypertonic solutions in, 1214
 Breast, accessory, fibroadenoma in, 830
 cancer of, treated exclusively by radiation therapy, 134
 inflammatory carcinoma of, 1075
 Bone sarcoma, types and treatment of, 123
 tumors, giant-cell, 122
 Bubo, 347
 Buck's extension (Bi.B.), 442
 Bunion and hallux valgus, 332
 Burns, 274
 scalp, in women, 389

Calculi, cystine, 581
 uric acid, 120
 Calculus, large vesical, vesical neck obstruction with. Bilateral hydroureters with hydronephrosis. Double left kidney and ureter, 836
 renal, caused by papilloma of skin, resembling roentgen-ray shadow, 103
 Calyx, sacculated, kidney resection for, 105
 Cancer of the breast treated exclusively by radiation therapy, 134
 early symptoms and diagnosis of, of genitourinary organs, 988
 of the lip and buccal mucous membrane, 593
 notes on the etiology of, 654
 rectal: principles and methods of treatment at the Memorial Hospital, 133
 Carbuncles, collodian treatment of, and boils, 371
 Carcinoma of the bladder; ureterosigmoidal implantation, total cystectomy, 1068
 of cloacal origin, 1627
 inflammatory, of the breast, 1075
 intra-oral epidermoid of, 136
 Care, medical, cost of, vs. value of medical service (E.), 437
 Cargile membrane in preventing intra-abdominal postoperative adhesions, 1012
 Caruncle, urethral, 403
 Causation, prevention and treatment of postoperative distention of the abdomen, 28
 Cement-starch mixtures as a substitute for plaster of Paris in the tropics, 1227
 Cervical lacerations and infections, 399
 Cervix, stenosis of, 399
 Cheek, unusual foreign body in, 1093
 Chirurgie (B.R.), 188
 der Brustorgane (B.R.), 909
 Child, nervous (B.R.), 1108

Chronic leg ulcers-treatment with Unna's paste boot, 743
 panostitis of cervical vertebrae, 1280
 Clavicle, fractured, 1086
 Clinic on malignant diseases—Memorial Hospital, N. Y., 122

Clinical consideration of intestinal obstruction, 509
 obstetrics (B.R.), 191
 and pathological aspects of appendicitis, 793
 radiology (E.), 439
 study of the abdominal cavity, 193, 459, 695, 911, 1109
 surgery, demonstrations of physical signs in (B.R.), 1107

Coagulation, tonsillar, versus electro-enucleation, 353
 Colles' fracture (Bi.B.), 169
 Collodian treatment of boils and carbuncles, 371
 Colon, fundamentals in roentgenology of, 844
 Common infections of the female urethra and cervix (B.R.), 189

Complications of spinal anesthesia, 1165
 Concealed hemorrhage following operation, 1183
 Conduction anesthesia for minor surgery, 239
 Congenital radioulnar synostosis, 429
 Conjunctivitis, management of, 396
 Contraception, abortion and (E.), 675
 Contractions, cicatricial, prevention of, 344
 Convenient marker for thyroid incisions, 597
 Cosmetic result in a case of marked scoliosis, 1081
 Cost of medical care vs. the value of medical service, (E.), 437

Cranio cerebral injuries, 1004
 Cyst (s), sebaceous, 364
 solitary, of the kidney with resection, 1290

Cystine calculi, 581
 Cystitis cystica, pyelitis, ureteritis, and,
 Cystourethroscope, new baby, experiences with, 102
 Cytological study of gonorrheal pus, 75
